Endotoxin is a potent activator of the complement cascade and for some years the peptide C5a was assumed to be centrally involved in neutrophil attraction to the lung in ARDS, since it is an effective neutrophil chemotaxin and secretagogue *in vitro* and is found in the blood of patients at risk of ARDS and of those with established disease [49]. However, lung macrophages do not produce C5a and levels of C5a in patients at risk do not correlate with the development of ARDS [49]. The current consensus is that chemokines, especially IL-8, play the key role in neutrophil chemoattraction to the lung in ARDS. However C5a, like many other mediators, probably exerts a number of powerful influences in the pathogenesis of ARDS, especially in combination with agents such as LPS [81].

There has been much less study of the role of the contact system that activates bradykinin and the clotting and fibrinolytic cascades, although these are likely to be important in the pathogenesis of ARDS. Activated kinins are vasoactive and cause increased vascular permeability. They can also act as secretagogues for neutrophils and other inflammatory cells.

#### *Cytokines*

Cytokines are a diverse group of soluble, hormone-like polypeptides produced by leucocytes and also by some constitutive tissue cells, especially macrophages, endothelial cells, epithelial cells and fibroblasts. It is likely that they play key roles at all stages of the evolution of ARDS. TNF- $\alpha$  and IL-1 are generated by alveolar macrophages on exposure to LPS and other stimuli of relevance to the pathogenesis of ARDS and are likely to play key roles in initiation [85–89]. These cytokines cause other resident cells, particularly epithelial and microvascular endothelial cells, to release IL-8 and other potent neutrophil chemokines. They also act on capillary endothelial cells to induce expression and activation of adhesion molecules necessary for neutrophil sequestration and for the creation of an injury-promoting microenvironment. Elevated levels of these agents have been found in association with ARDS [88,89]. TNF- $\alpha$  is not a good neutrophil secretagogue but like LPS it is a potent priming agent for subsequent neutrophil secretory responses.

Other cytokines, such as platelet-derived growth factor,

fibroblast growth factor and transforming growth factor  $\beta$ , are likely to play an important part in the vascular remodelling, fibroblast chemotaxis and fibroblast proliferation, and collagen synthesis that characterize the poorly understood fibroproliferative or chronic phase of ARDS.

#### *Chemokines*

This expanding family of small molecular weight peptides has received much recent attention. Depending on the position of cysteine in the molecule they have been subdivided into the C-X-C and C-C chemokines. The C-X-C subgroup contains a variety of peptides that are powerful neutrophil chemoattractants and activators, whereas the C-C group exert their chemotactic influences on monocytes and/or eosinophils. As discussed above it is now generally agreed that IL-8 and its family members are more likely to be responsible for neutrophil attraction to the lung in ARDS than C5a. IL-8 is an 8-kDa polypeptide that is a potent neutrophil chemoattractant and a powerful stimulus for endothelial cell chemotaxis and angiogenesis [90–92]. In personal studies of patients at the earliest stage of the risk period for ARDS, of a plethora of candidates studied IL-8 was the only mediator to correlate with development of ARDS [58]. Other chemokines are likely to play important roles in subsequent monocyte emigration but these are less well characterized.

#### *Membrane phospholipid derivatives*

Membrane phospholipid derivatives, including platelet-activating factor (PAF), leukotrienes, prostaglandins and prostacyclin, may influence inflammatory cells (PAF is an important neutrophil priming agent), but they also exert major influences on local blood vessels and promote the generation of oedema fluid. Thromboxanes can cause marked pulmonary vasoconstriction and may be partly responsible for the pulmonary hypertension that characterizes the early stages of ARDS.

#### ***An injury-promoting microenvironment between abnormally sequestered neutrophils and pulmonary capillary endothelial cells***

Neutrophils do not injure endothelial cells *in vitro* without direct contact, and it is likely that stimulated neutrophils interact with endothelium in such a way as to lead to the formation of a specialized intercellular microenvironment within which concentrations of histotoxic agents, such as enzymes and ROI, would reach high levels whereas their high molecular weight inhibitors would be relatively excluded. Furthermore, many potent neutrophil enzymes such as elastase are preferentially located on the leading surface of the cell and need close apposition in order to cause effects. Finally, some of the most active ROI are so

labile that they are able to act over very short tissue distances (Fig. 27.10). This concept of a restricted intercellular microenvironment necessary for neutrophil-mediated injury is supported by experiments showing that matrix degradation in areas where stimulated neutrophils are tightly adherent continues in the presence of the large molecular weight antiproteinase  $\alpha_1$ -proteinase inhibitor [93]. The creation of such a microenvironment between neutrophils and endothelial cells in lung capillaries is likely to occur because of a combination of adhesion mechanisms and alterations in neutrophil rheological properties, particularly reduction in deformability.

#### Neutrophil-endothelial surface adhesive molecules

Adhesion between neutrophils and endothelial cells *in vitro* is greatly enhanced within minutes of the addition of inflammatory mediators such as C5a or PAF [94]. Much of this enhanced adhesion can be abolished by monoclonal antibodies directed against the CD11/18 group of adhesive leucoproteins on the neutrophil surface. A number of inflammatory cytokines increase the expression of neutrophil adhesion molecules that are of relevance for their interaction with endothelial cells. Similarly, endothelial cells that have been activated by LPS or cytokines express adhesion molecules on their surface, and others that are already expressed become activated. *In vivo* it is likely that neutrophil adhesion to endothelial cells in microvessels occurs by a complex process involving at least two phases. In the first, transient phase of adhesion (which is nevertheless necessary for the second phase), interactions between molecules of the selectin family on neutrophils and endothelial cells are particularly important. In the second phase of tight adhesion, necessary for the creation of an injurious microenvironment and also for capillary trans-

migration of neutrophils, integrin molecules play the central role. In considering this pro-injury microenvironment it is also important to consider its kinetic aspects. For example, a neutrophil in contact with a pulmonary capillary endothelial cell for a few microseconds is a very different proposition to an activated secreting neutrophil in contact with the endothelium for several seconds. Experiments in which low concentrations of endotoxin and chemotactic peptides induce acute lung injury in the rabbit show that these agents, when combined, greatly enhance the time of contact of neutrophils with the lung microvessels [50,52].

#### Reduced neutrophil deformability

As discussed above, neutrophils are normally required to squeeze through the narrow lung capillaries, and any factors that reduce neutrophil deformability would significantly increase their time of sequestration and thereby increase the time of contact between activated or secreting neutrophils and the vulnerable gas-exchange membrane. Although it has been widely considered that abnormal sequestration occurs mainly via upregulation of neutrophil and endothelial surface adhesive molecules, alteration in neutrophil deformability is also likely to play an important role in the particular setting of the pulmonary circulation. It has been shown that neutrophils treated with relevant inflammatory mediators are retained abnormally on filters with a pore diameter of 5  $\mu\text{m}$  by a mechanism that does not involve CD11/18 but which is abolished by cytochalasin D, suggesting a role for the cytoskeleton [80,95]. Direct measurements showed that these cells had markedly reduced deformability *in vitro* and, when injected intravenously, had prolonged residence time in the pulmonary microcirculation [96]. The

**Fig. 27.10** Concept of a restricted pericellular microenvironment favouring tissue injury at the neutrophil-endothelial interface.

mechanisms involved in neutrophil deformability are much less well understood than the molecular mechanisms relating to the expression of adhesion molecules. However a full understanding of pathogenesis and its potential therapeutic manipulation requires that these mechanisms receive more research attention.

### Neutrophil priming, triggering and secretion of injurious products

Even when neutrophils are tightly apposed to matrix proteins or endothelial cells *in vitro*, the induction of neutrophil-mediated injury is not an all-or-nothing phenomenon. When neutrophils are prepared by stringent methods that avoid their exposure to ubiquitous LPS or other agents that might influence their function, stimulation with secretagogues such as C5a or formylmethionine leucyl-phenylalanine (fMLP) may cause little or no release of ROI or enzymes. However if these cells are previously exposed to low concentrations of LPS, which does not cause secretion itself, subsequent exposure to fMLP causes major release of ROI and granule enzymes [97,98]. These priming and triggering phenomena have a number of implications for tissue injury. Firstly, the presence *per se* of

neutrophils in tissue does not equate with injury and it is likely that they need to be primed and triggered to achieve a maximal secretory state. Secondly, when examined in this context, many of the mediators implicated in the pathogenesis of ARDS exert different effects, for example LPS, TNF- $\alpha$  and PAF are poor secretagogues but highly effective priming agents, whereas C5a, IL-8 and leukotriene B<sub>4</sub> and other neutrophil chemotaxins are potent secretagogues for primed cells [99,100]. Furthermore, in studies of neutrophil-mediated injury *in vitro* using stringently prepared neutrophils, it has been found that both LPS and C5a (or fMLP) are required for injury to occur, while *in vivo* this combination of agents is needed to induce neutrophil-mediated endothelial injury [51,52].

Therefore, rather than seeking a single common mediator it is perhaps more important to define how certain key mediators act together to influence critical mechanistic events such as neutrophil secretion. In this regard, the intracellular pathways responsible for neutrophil priming, activation and secretion are partially understood (Fig. 27.11) but little is known of how agents that prime neutrophils influence these events. While priming agents including LPS do not cause significant secretion they do exert other influences on neutrophil behaviour, including

**Fig. 27.11** (a) The concept of neutrophil priming. (b) Release of superoxide and lysozyme by neutrophils primed by lipopolysaccharide. (Data from Guthrie *et al.* [97] and Haslett *et al.* [98].)

reduction in deformability and increased adhesivity, which may be extremely important in determining the degree and longevity of neutrophil sequestration in pulmonary capillaries [95]. Indeed, in one of the *in vivo* studies mentioned above the addition of LPS, necessary for C5a-induced lung injury, greatly increased the time of contact between neutrophils (presumably primed and triggered) and pulmonary capillary endothelium [50].

When the vast array of potentially injurious neutrophil products (Table 27.6) is considered, it is clear that there is remarkable redundancy of the inflammatory response. Most of these products have probably evolved to assist the neutrophil in its rapid passage to the inflamed/infected site and in effective killing of bacteria; however, in neutrophil-mediated tissue injury and disease processes the difficulty of identifying centrally important toxic

agents cannot be exaggerated. Much circumstantial evidence has accrued to support a role for neutrophil-generated ROI in ARDS [72]. However, studies in the early risk period suggest that neutrophil elastase is also an important agent; in an *in vitro* study of neutrophil-mediated endothelial injury using neutrophil stimuli of relevance to the pathogenesis of ARDS, inhibitors of ROI alone were not effective in blocking injury, whereas a specific neutrophil elastase inhibitor exerted major inhibitory effects [51,56]. At present it seems that an effective therapeutic strategy directed against neutrophil toxic products would need to include both antiproteinase and antioxidant elements.

### Outcome of acute lung injury: resolution of inflammation and repair or progression of disease

Many of the 50% who survive ARDS appear to regain useful lung function, and it is implicit that there must be effective mechanisms whereby acute inflammation can resolve and injury can be repaired. However, by contrast with the amount of research devoted to the initiation mechanisms of inflammation, this topic has received comparatively little attention until recently. Thus the circumstances whereby the resolution and repair mechanisms fail and a chronic inflammatory phase develops, together with an excessive or inappropriate fibroproliferative response, remains a mystery not only for ARDS but for a whole spectrum of chronic inflammatory/scarring diseases in the lungs and other organs.

### Resolution of acute inflammation

For lung tissues to return to normal, all the processes that occur during the evolution of acute inflammation must be reversed, including removal of the inciting stimuli, dissipation of mediators, cessation of granulocyte emigration from blood vessels, restoration of normal microvascular permeability, cessation of monocyte emigration from blood vessels and their maturation into macrophages, removal of extravasated fluid, proteins, bacterial and cellular debris, removal of extravasated neutrophils and inflammatory macrophages, and replacement and repair of any damaged cells or tissues.

Factors involved in the cessation of inflammatory cell migration into tissues are poorly understood, although neutrophil emigration is known to cease very rapidly in the evolution of self-limited acute inflammatory responses in the lung and yet this mechanism for inhibition of neutrophil emigration appears to fail in chronic inflammatory conditions associated with lung fibrosis [101,102]. Whether the normal cessation of neutrophil emigration is due to dissipation of chemotaxins or the generation of chemotactic factor inhibitory agents remains uncertain. Similarly, the processes whereby neutrophils are removed from tissues have received little attention until recently.

Because neutrophils and other inflammatory cells contain such a huge armamentarium of histotoxic agents and because the kinetics of their removal determines tissue residence time just as importantly as their rate of emigration, it is important that removal mechanisms and their influences are elucidated. It has been assumed that neutrophil granulocytes undergo necrosis and disintegrate at the inflamed site [103], although this would inevitably expose healthy tissue to large concentrations of potentially injurious neutrophil contents. However, an alternative tissue fate has been described, whereby extravasated neutrophils undergo apoptosis or programmed cell death [104,105]. This process is responsible for the physiological removal of unwanted cells in a whole range of tissues, including embryonic remodelling and the removal of cells from the gut crypts. In the granulocyte, apoptosis leads to shut-down of the secretory apparatus and removal of intact cells that retain their granule contents by inflammatory macrophages, which use a phagocytic recognition mechanism that fails to activate the macrophage or to provoke it to secrete proinflammatory mediators [105–110]. This ‘silent’ removal process is under a number of controls. The ‘suicide’ programme of the granulocyte can be inhibited by a range of important inflammatory mediators [111]; indeed it is likely that apoptosis is the major mechanism controlling the longevity of neutrophil and eosinophil granulocytes in inflamed tissues. Although the neutrophil and eosinophil are closely related developmentally, different mediators influence their apoptotic programme; for example both are inhibited by granulocyte-macrophage colony-stimulating factor, whereas IL-5 selectively inhibits eosinophil apoptosis and LPS selectively inhibits neutrophil apoptosis [112]. Furthermore it has been discovered that apoptosis can be induced by a variety of ‘death receptors’ that may be used differently by different cell types. For example, neutrophil apoptosis is promoted by TNF- $\alpha$  but not by corticosteroids whereas corticosteroids accelerate eosinophil apoptosis [110,113], while apoptosis in both granulocyte types is induced by ligation of the Fas surface receptor. It is possible that these different responses to death receptor ligation and the different survival factors could be employed therapeutically to remove certain cell types by the mechanism which nature intended (see below). It is also clear that macrophage clearance of apoptotic cells is under a series of controls; for example cationic proteins and low pH inhibit clearance, whereas certain cytokines, corticosteroids and CD44 ligation promote macrophage clearance of apoptotic cells [107,114].

### Repair

Even in ‘beneficial’ inflammation, as exemplified by the inflammatory response to the pneumococcus in the pathology of lobar pneumonia, there is evidence of

destruction of endothelial and epithelial cells; yet in the recovery phase of lobar pneumonia it is clear that the damaged epithelial–endothelial linings can be reconstituted with no significant evidence of a scarring response [101]. Individual cells are likely to be replaced by their neighbours but when significant numbers of cells are lost in more extensive injury there must be local cellular proliferation to reconstitute the cellular layer. Endothelial cell monolayers *in vitro* appear to be able to recover from hydrogen peroxide-mediated injury by a mechanism requiring protein synthesis [115]. Epithelial monolayers also display a remarkable capacity to regenerate, although after extensive type I epithelial cell injury it is the type II pneumocytes that proliferate to reconstitute the epithelial barrier. Type II cell proliferation is a common and often early finding in the natural history of ARDS [62], indicating that the evolution of the disease is a continuous balance between repeated injurious insults and attempts at repair.

Most pathologists agree that the extent of epithelial injury is critical in determining whether the lung attempts to heal by reconstitution of the epithelial lining or by fibrosis.

### Pathophysiology

Gas dilution studies have shown that only one-third to one-half of the total lung volume is filled with gas in patients with acute lung injury. The use of CT has revealed that most of the alveolar oedema fluid is distributed to the dependent parts of the lungs, and sometimes moving the patient to the prone position can improve gas exchange. Other studies have suggested that the distribution of oedema is more uniform in patients who are ventilated by high-frequency jet ventilation, which suggests that the mode of ventilation may also have an important influence.

Other pathophysiological consequences may result from surfactant production, which is disordered both in volume and quality, perhaps the result of dysfunctional type II cells in acute lung injury. Qualitative changes in surfactant may be sensitive markers of early alveolar injury and in some studies surfactant alterations in the risk period and early stages of ARDS correlate with the severity of lung function changes in full-blown disease. Progressive alterations in the percentage composition of certain phospholipids during the later stages of the natural history of ARDS have been observed but their functional significance is uncertain [116–119]. Surfactant function may also be detrimentally influenced by ROI and phospholipases released locally by neutrophils and other inflammatory cells; it is also likely that the high protein concentration in the inflammatory exudate markedly impairs surfactant function. These qualitative and quantitative changes in surfactant composition and the adverse influences on surfactant function undoubtedly make a

major contribution to the atelectasis, reduced functional residual capacity, reduced compliance and increased shunt found in established ARDS. However, there may be other changes in surfactant function that relate to other aspects of lung disease in ARDS. In particular much less is known about the changes in surfactant protein composition and function in ARDS. These proteins (Sp-A, Sp-B, Sp-C, Sp-D) have recently been subjected to more detailed study (see Chapter 4) and have been found to opsonize bacteria and to exert effects on inflammatory cells including macrophages [120,121]. It is possible that quantitative or qualitative changes in these proteins could have secondary influences particularly on host defence in the damaged lung, which is especially prone to secondary and often devastating infections with Gram-negative and other bacteria.

Pulmonary hypertension is a common complication of the early stages of ARDS. It contributes to pulmonary oedema and is associated with increased mortality [33,122]. In the early stages it is probably the result of vasoconstrictor mediator release. In the late stages it may occur as a result of pulmonary thromboembolism or remodelling of the injured lung. Pulmonary hypertension may also contribute to right ventricular dysfunction, although poorly characterized circulating factors also directly depress the myocardial contractility of both the right and left ventricles [123]. At different stages of ARDS augmented hypoxic pulmonary vasoconstriction and loss of the normal hypoxic vasoconstrictor response are thought to play a role in the development of pulmonary hypertension and increased right-to-left shunting respectively [124]. Decreased cardiac output in patients with ARDS may lead to impaired oxygen delivery to tissues, even in the presence of a normal  $P_{aO_2}$  [125,126]. This problem may be compounded by impaired tissue oxygen uptake, which is particularly common in patients with sepsis for example and which may occur as a result of tissue oedema, microembolization of capillaries and loss of local microvascular control mechanisms. Finally, to make matters worse, in many of these patients there is an increased tissue oxygen demand as a result of fever and tissue inflammation and repair processes.

### Clinical features and diagnosis

The patient develops progressive dyspnoea and often a non-productive cough, usually several hours or days after a recognized predisposing condition. Generally, clinically overt ARDS develops more rapidly (hours) after direct insults to the lung, such as inhalation of toxic gases or aspiration of gastric contents, than after indirect insults such as Gram-negative septicaemia or multiple trauma (24–48h). On examination the patient is tachypnoeic and often cyanosed and agitated. Tachycardia is likely to be present but the jugular pressure is not elevated [1,2]. Scat-

tered inspiratory crepitations may be heard on auscultation but this is not a constant feature.

The chest radiograph typically shows fluffy areas of opacification either throughout the lung (see Fig. 27.3) or predominantly peripherally [1,2,127]. Air bronchograms are common but Kerley's lines, pleural effusions and dilatation of upper zone vessels are rare. Thus there are a number of radiological features that can help differentiate ARDS from pulmonary oedema due to left ventricular failure (see Table 27.2), although the distinction is not always easy. Equally, distinguishing ARDS from diffuse pneumonia may be difficult: not only can the radiological features be virtually identical (e.g. in *Pneumocystis carinii* pneumonia) but pneumonia is also both a recognized cause and a complication of ARDS. Therefore, while patients can be categorized as suffering from ARDS according to the consensus criteria, it is often necessary for the clinical management to exclude cardiac failure and primary pneumonias. With regard to the former, it may be necessary to obtain a pulmonary capillary wedge pressure (normal or low in ARDS, elevated in left ventricular failure) and very occasionally a video-assisted thoracoscopic lung biopsy may be needed to exclude other causes of interstitial shadowing, especially pneumonia.

### Management

Although new therapeutic approaches may be on the horizon, the current treatment of ARDS remains supportive. The trend towards improvement in mortality has undoubtedly been the result of general advances in intensive care over the past decade or so. Because of the wide variation in patient subgroups, ventilatory techniques and other aspects of ITU management, there is as yet no widely accepted single protocol for managing ARDS. The general principles rest on the maintenance of mixed venous oxygen saturation and the function of other organs such as the kidneys, together with a readiness to diagnosis and treat potentially lethal infective complications.

### Respiratory support

Some of the technical aspects of the various approaches that have attempted to improve gas exchange and tissue oxygenation in patients with ARDS are discussed in Chapter 58, and the interested reader is referred to several excellent reviews of this topic [128–134]. One of the problems with conventional methods of respiratory support and oxygen delivery is that mechanical ventilation itself and the high concentrations of inspired oxygen necessary may both exacerbate lung injury, while the high airway pressures needed to ventilate these patients may result in barotrauma, reduced cardiac output and reduced oxygen delivery. The decision to place a patient with ARDS on mechanical ventilation, given these possible complica-

tions, depends on a variety of clinical factors including worsening gas exchange and impending exhaustion. Most patients are supported by intermittent positive pressure ventilation often combined with positive end-expiratory pressure (PEEP, 5–20 cmH<sub>2</sub>O), which may decrease shunt by reducing alveolar collapse, increasing compliance and functional residual capacity. However, there is no hard evidence that PEEP alters the clinical course of ARDS. High PEEP often leads to reduced cardiac output, and large tidal volumes may be required to counteract the increasing physiological dead space. Furthermore, the resultant high inflation pressures greatly increase the risk of barotrauma, including pneumothorax and pneumomediastinum.

A number of new ventilatory strategies have been used in an attempt to maintain airway pressures while at the same time limiting peak inspiratory pressures. These include high-frequency jet ventilation, which maximizes alveolar recruitment at lower peak inspiratory pressures [133], and inverse ratio ventilation, which works on the principle of prolonging the inspiratory time to the point of reversing the inspiratory–expiratory ratio, with similar effects on pathophysiology [134]. Temporary improvements in gas exchange may accrue by turning patients with acute lung injury to the prone position [135]. However, it is not yet established whether any of these techniques reduce mortality, since there have been few controlled trials comparing them with conventional respiratory support.

Because of the acknowledged limitations of mechanical ventilation with high  $F_{IO_2}$ , attempts have been made to develop methods of extrapulmonary gas exchange, such as extracorporeal membrane oxygenation [136,137]. However, these techniques are expensive, only available in specialist centres and associated with their own set of complications, including sepsis, coagulopathy and haemorrhage. Their benefits are still not fully established in clinical trials but because of their long-term potential for support of patients of this type there is considerable ongoing research.

## Non-respiratory support

### Infective complications

One of the gravest complications of ARDS is nosocomial infection of the injured lung, which has an associated mortality rate approaching 90% [138]. There are a number of reasons why this condition is very difficult to recognize, assess and treat in established ARDS: (i) pneumonia itself is a common risk factor for ARDS; (ii) by definition the chest film in ARDS already shows widespread pulmonary infiltrations; (iii) ARDS itself may lead to fever and leucocytosis in the absence of secondary infection; and (iv) colonization of the upper airways of intubated ventilated

patients increases with the duration of mechanical ventilation. While it is important to resist the temptation to treat all patients with broad-spectrum antibiotics based on clinical suspicion or cultures from tracheal aspirates alone, it is imperative that potentially fatal infections are recognized and treated promptly and aggressively. Most centres recommend sampling using the protected specimen bronchial brush via the fiberoptic bronchoscope or BAL via the fiberoptic bronchoscope [139,140]. The most common organisms implicated in nosocomial pneumonia are Gram negative, particularly *Pseudomonas aeruginosa* [141].

### Fluid balance

Expert management of fluid balance is critical in order to avoid causing an increase in capillary hydrostatic pressure and thus exacerbating pulmonary alveolar oedema. While the achievement of negative fluid balance can result in a reduction of alveolar oedema and improved outcome, it can also be complicated by a reduction in cardiac output, reduced oxygen delivery to tissues and renal failure. In order to maintain cardiac output and oxygen delivery to tissues and at the same time reduce pulmonary artery pressure, complex and often empirical manipulations of fluid balance, the use of loop diuretics and haemofiltration are often necessary. Early attention must be paid to nutritional support, particularly in septic patients, and feeding via a jejunal tube may help maintain gut mucosal integrity.

## Drug therapy

### Pulmonary vasodilators

Theoretically these should reduce right ventricular afterload and thereby improve cardiac output and tissue oxygen delivery. However, trials with nitrates failed to improve oxygen delivery and a multicentre trial of prostaglandin E<sub>1</sub> did not improve mortality rates [142–144]. One of the problems with intravenously delivered vasodilators is that they also dilate vessels supplying non-oxygenated lung, thus worsening the shunt problem. More recently, inhaled nitric oxide has been advocated as a therapy that should selectively dilate vessels supplying aerated lung, thereby improving ventilation–perfusion matching. Early experience has shown a prolonged haemodynamic benefit from this form of treatment with no evidence of toxicity [145,146], although whether these improvements in pathophysiology result in reduced mortality remains to be established.

### Exogenous surfactant therapy

Encouraged by trials suggesting that the intrapulmonary

instillation of exogenous bovine or synthetic surfactant improves outcome in neonatal respiratory distress syndrome [147], this approach has been recently applied to patients with ARDS. However, there are difficulties with the mode of administration in achieving widespread delivery to the small airspaces of the lung and trials so far have not been particularly encouraging [148].

#### *Anti-inflammatory therapy*

In the risk period and in the early stages of established ARDS, well-conducted multicentre trials have shown that despite their multiple effects in various inflammatory cascades, corticosteroids are of no benefit and may even have detrimental infective complications [149,150]. However, intriguing new studies, which require to be extended and confirmed, suggest that there may be a previously unsuspected role for corticosteroids in the treatment of ARDS. There are now several reports of their potential benefit in late ARDS, particularly in the fibroproliferative chronic stage [151–153]. As discussed above, antiendotoxin antibody therapy in patients with sepsis syndrome has no major overall benefit. Pentoxifylline, a methylxanthine derivative that reduces both the production of TNF- $\alpha$  and IL-1 and their biological effects on inflammatory cells, has proved beneficial in animal models, but its place in the clinical management of ARDS remains to be established.

So far, no attempt at manipulation of the inflammatory mechanisms involved in pathogenesis or of the pathophysiological events has proved to have a beneficial influence on the outcome in ARDS (Table 27.7). Nevertheless, as discussed above, recent advances in the understanding of the mechanisms of ARDS may lead to novel therapeutic strategies, and perhaps advances in the techniques of extracorporeal oxygenation may ultimately be clinically applicable. It is clear that multiple approaches could be taken against a whole range of cytokines, chemokines, adhesion molecules and inflammatory cell products, and

it is likely that many potential therapeutic candidates will emerge from the burgeoning biotechnology industry over the next decade. It is difficult to be certain which are the appropriate candidates to be tested in the large multicentre trials of well-defined subgroups of ARDS patients that will be required to establish efficacy without unacceptable detrimental effects on host defence, particularly against bacterial infection.

#### *Prospects for new mechanism-based therapy*

As discussed, most of the steady reduction in mortality over recent years is probably the result of gradual improvement in ITU management, and attempts at anti-inflammatory therapy have not been helpful so far (see Table 27.7). The use of corticosteroids in established disease and in the risk period has proved disappointing and has even been associated with detrimental effects; thus treatment remains supportive. However recent advances in our understanding of the early mechanisms of disease may provide an opportunity to develop new therapeutic approaches, which could be applied in high-risk subgroups of patients, particularly in the risk period before the full-blown complex disease is established. A number of approaches could be taken.

Certain key mediators could be targeted. However, it will be important to establish the stage of pathogenesis when that factor is most vulnerable, e.g. anti-LPS strategies have probably been applied too late in the pathogenesis of septic shock (see below). Based on recent evidence, it appears that IL-8 may be centrally important in the pathogenesis of ARDS but, again, it may need to be inhibited early in the risk period.

The processes whereby neutrophils sequester in pulmonary capillaries, including those involved in adherence to endothelial cells, could be manipulated. The mechanisms responsible for reduced deformability are poorly understood at present, although the molecular characterization of adhesion molecules required for neutrophil-

High-frequency jet ventilation	Less barotrauma, but no proven survival benefit	Keogh <i>et al.</i> [133], MacIntyre <i>et al.</i> [158]

endothelial adherence are receiving much attention. The use of monoclonal antibodies that block adhesion molecules is an expensive approach and perhaps the antibody molecules may be too large for effective accessibility to the intercellular microenvironments. However, the molecular engineering of peptides that block key sites of adhesion molecule ligation may provide new drugs in the near future. There have been suggestions that different components of the adhesion molecule repertoire may be employed during different physiological processes in different organs [159]. This suggests the exciting possibility that in the longer term it may be possible to block neutrophil adhesion molecules needed for migration to sites where they are involved in disease pathogenesis, while perhaps retaining their ability to migrate to other sites for the purpose of host defence.

It may be possible to block key neutrophil injurious products. However, in this prime example of redundancy, which ones should be blocked? There is much circumstantial evidence that ROI generated by neutrophils and other inflammatory cells are centrally important in pathogenesis and there is increasing recent evidence that neutrophil elastase may be an important target.

By now, it should be appreciated that any approach (including all three mentioned above) that would effectively wipe out the neutrophil effector pathway has a major drawback, namely the loss of these highly effective mechanisms in host defence, particularly against bacteria. While this consideration may be more important in chronic inflammatory diseases and may represent less of a problem in acute tissue injury syndromes such as ARDS (in which patients could be supported during the application of such therapies for a few days), it must be remembered that injured, burned and septic patients are likely to be particularly at risk from potentially life-threatening infections; it is of interest that much of the increased morbidity and mortality observed in the multicentre studies of corticosteroid therapy in ARDS were associated with infective complications [149,150]. As we learn more about the inflammatory response it seems clear that the very same mechanisms that evolved to protect the host against bacterial invasion are turned against the host in the pathogenesis of inflammatory diseases, and it is unlikely that we will be able to dissect the mainly detrimental mechanisms from those crucially involved in host defence. Thus inflammation is a double-edged sword, and this paradox, together with the very many redundant mechanisms, are perhaps the biggest problems in the design of anti-inflammatory strategies.

Nevertheless, other approaches could be taken which might not have the same implications for host defence. It has become clear that epithelial cells and endothelial cells *in vitro* and *in vivo* have the capacity to resist a certain amount of oxidative and/or protease-mediated damage. We are beginning to learn more about these cytoprotective

mechanisms, for example the role of glutathione and small molecular weight antiproteinases such as secretory leuko-proteinase inhibitor and elafin. In the future it may be possible, in the ARDS risk period for example, to augment the production of such protective mechanisms by the endothelial and epithelial cells themselves using pharmacological or gene-therapeutic approaches [160].

It may also be possible to harness the poorly understood mechanisms whereby acute inflammation normally resolves spontaneously. By contrast with initiation mechanisms, this side of the inflammatory equation has been subjected to far less research. However, it now seems clear that apoptosis is a key mechanism controlling the functional longevity of neutrophils and other granulocytes at the inflamed sites. As discussed above, in granulocytes apoptosis leads to cessation of secretion and to their silent removal by local macrophages. When more is known about the selective use of different death receptors or the induction of apoptosis in different cell types it may be possible to induce the selective removal of neutrophil granulocytes at an appropriate stage in the pathogenesis of ARDS. Finally, recent studies have suggested that anti-inflammatory cytokines may be important in the outcome of established ARDS. In studies of the risk period it appears that while IL-8 is a key predictive and mechanistic factor involved in whether patients progress to full-blown disease, once the diagnosis of ARDS is established the levels of IL-8 in blood or BAL fluid or of any other proinflammatory mediator are related to outcome. This has led to speculation that in established disease certain anti-inflammatory cytokines, such as IL-1 receptor antagonist or IL-10, may dictate outcome. Indeed, research on patients with established ARDS shows that mortality appears to be associated with lower levels of IL-1 receptor antagonist and IL-10 in BAL fluid compared with those who survive [161]. Thus it is possible that outcome is more related to the patient's ability to mount an effective anti-inflammatory cytokine response, which might then permit resolution and repair processes to take over. These studies need to be confirmed and extended but, if correct, suggest a future therapeutic strategy whereby an ineffective anti-inflammatory cytokine response could be remedied, perhaps by genetic augmentation of their production in the lung tissues of ARDS patients.

## **Outcome of ARDS: its natural history and sequelae**

### **Mortality**

Most studies have indicated a mortality rate of 50–70% [162–164], with little change since the syndrome was first described 30 years ago. However, some recent longitudinal studies suggest a fall in mortality. In one single-centre study there was a reduction in mortality from 54% to 40%

between 1983 and 1992, a trend that was confirmed in a recent multicentre report [34,165]. These observations were not accounted for by changes in the patient population in terms of age, sex, injury severity score (in trauma) or risk subgroups. Factors associated with mortality include the following.

1 Development of acute multiple organ failure: in patients who develop non-pulmonary organ dysfunction between hospital and ITU admission the mortality approaches 90%, whereas it is about 50% in those patients with respiratory failure only [166].

2 Severity of ARDS and early response to treatment: those patients with the best static lung compliance and major rapid improvement in arterial oxygenation are most likely to recover [167].

3 Predisposing condition: 20–45% of patients with sepsis syndrome develop ARDS and 70–90% of these die, compared with a mortality rate of about 10% in ARDS due to fat embolism [167–171].

4 Presence of underlying disease, for example cirrhosis or malignancy, is associated with a worse prognosis [172].

5 Age: in patients who are aged over 60 mortality is about 75%, in those aged 50–59 it is 62% and in those aged 16–49 it is 37% [165,173].

6 Markers of inflammation and injury: in general the presence of inflammatory mediators in the lungs and their concentration therein have not been helpful in predicting the outcome of established ARDS. These include TNF- $\alpha$ , IL-1, IL-8 and a range of other chemokines and circulating soluble endothelial adhesion molecules, including von Willebrand factor antigen and E-selectin. It may seem surprising that there appears to be no relationship between a wide range of proinflammatory mediators and disease outcome. However, the recent observation that low levels of anti-inflammatory agents, such as IL-1 receptor antagonist and IL-10, correlate closely with mortality suggests that an effective anti-inflammatory cytokine response may be a more important determinant of recovery [161]. Markers that relate to an effective inflammatory resolution and repair response, such as pro-apoptotic factors, remain to be evaluated.

Death in most patients with ARDS is due to the development of multiple organ failure or nosocomial pneumonia and further episodes of sepsis rather than to intractable respiratory failure *per se*. As discussed above there is no evidence that any pharmacological intervention over and above high-quality intensive care has any influence on outcome. There is a great need for better indicators of outcome, whether these relate directly to the disease process or are surrogate markers. Because the number of ARDS patients in any single centre is small, these indicators will need to be established by consensus in multicentre cooperative groups. Reliable outcome data are critical not only for the assessment of new forms of therapy but also for identifying those patients likely to benefit from

intensive care as against those in whom the outlook is presently hopeless.

### Sequelae

One study of pulmonary function in ARDS survivors showed that 4% of patients were severely impaired and 15% were moderately impaired a year later; remarkably, particularly when the histopathology of this condition is considered, around 50% of patients showed only mild impairment and 30% returned to apparently normal function [174]. Long-term pulmonary dysfunction is associated with a high  $F_{IO_2}$  and severe hypoxaemia during the ARDS episode as well as with the patient's age and smoking history [175].

The remarkable recovery of pulmonary function demonstrated by most survivors suggests that when the natural processes of resolution of inflammation and repair are better understood we should gain new therapeutic insights that could be applied to patients with established ARDS. The promotion of naturally available resolution and repair mechanisms should have no potential detriment to host defence against bacterial infection.

### Neurogenic pulmonary oedema

Pulmonary oedema occasionally occurs as a sequel to intracerebral disease [176]. Described initially following epileptic seizures, it is now known to occur after head trauma, intracerebral and subarachnoid haemorrhage and neurosurgery. The common aetiological factor seems to be an acute rise in intracranial pressure. This may be followed immediately or within a few hours by acute pulmonary oedema, though occasionally the onset of oedema is slowly progressive over several days. In the former case it is often relatively benign and short-lived, resolving spontaneously within 48h. However, sometimes it may be severe and fatal. Studies of lung water, carried out prospectively in patients with serious head injuries and subarachnoid haemorrhage, have shown that accumulation of fluid is a frequent event, occurring in up to 50% of patients [177].

The condition presents with breathlessness, cough and sometimes haemoptysis some hours after the cerebral episode. In most cases it reduces spontaneously, requiring only supplemental oxygen. Sometimes assisted ventilation is necessary to overcome hypoxaemia, although PEEP should be avoided as it increases intracranial pressures and decreases cerebral perfusion. As far as possible, attention should be directed to alleviating the primary cause and reducing intracranial pressure.

Neurogenic pulmonary oedema is considered separately because there is evidence that both hydrostatic factors and increased permeability play a part in its aetiology. An acute rise in intracranial pressure may cause

increased sympathetic discharge and a rise in levels of circulating catecholamines in the blood. This may cause acute left ventricular failure as a result of increased venous return, shortened contraction time and systemic vasoconstriction, probably due to  $\alpha$ -adrenergic stimulation. Pulmonary vasoconstriction may also occur in these circumstances, and this has been shown to be a response to catecholamine release following raised intracranial pressure in animal models [178,179]. These changes may combine to alter the balance of the Starling equation towards oedema formation. However, there is clinical evidence that the oedema fluid may contain relatively high levels of protein and that oedema can occur in the absence of raised pulmonary pressures [6,180]. This evidence of increased vascular permeability in humans is consistent with findings in animal studies [181], and suggests that other factors must be, at least in some cases, acting directly on the endothelium. What these are remain a mystery. Sometimes they may be related to a sudden acute rise in capillary pressure causing a type of 'blast injury' [178]; or they may be other humoral mediators and, again,  $\alpha$ -adrenergic agents may be responsible [182].

### High-altitude pulmonary oedema

A proportion of people ascending to high altitudes develop acute mountain sickness, a syndrome in which the traveller or climber feels generally unwell, nauseated, anorexic, lethargic and dizzy [183–185]. Headache and vomiting are common symptoms. While this condition usually settles spontaneously with rest in a few days, a few develop high-altitude pulmonary oedema. This usually starts within 3–96 h of ascent [185,186] and is rare below about 3000 m. It is more common in younger people and seems to occur in proportion to the rate of ascent, the exertion required to ascend and the altitude reached. There is anecdotal evidence that people who have experienced acute mountain sickness are liable to suffer from it again, and some are clearly so susceptible that they should avoid high altitudes altogether. It is particularly common in high-altitude dwellers returning home after a spell at sea level [187,188].

The condition may be accompanied by cerebral oedema, in which case the patient becomes confused and stuporose, eventually lapsing into coma [189]; it seems likely that the three components of high-altitude sickness, acute mountain sickness and pulmonary and cerebral oedema, are closely associated. Increases in cerebral and retinal blood flow and retinal haemorrhages occur very commonly at high altitudes [190–192], and papilloedema occurs in patients with the cerebral syndrome.

Pathological studies of fatal cases of high-altitude pulmonary oedema are sparse. They have shown the expected congestion of the lungs, with pink froth in the airways, proteinaceous alveolar fluid and hyaline mem-

branes [193,194]. Pulmonary arterial thromboses and bronchopneumonia are frequent features of fatal cases, most of whom also have well-marked cerebral oedema.

The aetiology of high-altitude pulmonary oedema is obscure. It is clearly related to hypoxia and may also be exacerbated by the cold conditions and exertion invariably associated with altitude. One physiological response to hypoxia and to exercise is fluid retention, with a shift of fluid from the systemic to the pulmonary circulation and an increase in pulmonary arterial pressure. The mechanisms of this are not understood, although it has been suggested that there are alterations in the renin–aldosterone response, perhaps as a result of hypoxia interfering with the production of angiotensin-converting enzyme in susceptible individuals [195,196]. Studies of pulmonary oedema fluid and BAL specimens have shown that the fluid from the lungs contains red blood cells and has a high protein content, indicating that the oedema is of the increased permeability type [183]. On the other hand, there is little evidence that an inflammatory reaction has occurred in the lungs, suggesting a similar mechanism to that of neurogenic pulmonary oedema. One hypothesis proposes that hypoxic vasoconstriction in some parts of the lung results in much increased flow and pressure in other parts, resulting in high-pressure damage to capillary endothelium. Why some people develop the disease and others do not may be related to different responses of the medullary respiratory centres to hypoxic stimuli; studies have shown that individuals who have had high-altitude pulmonary oedema have a reduced ventilatory response to hypoxia [183].

Whatever the aetiological mechanisms, the condition usually responds promptly to the increased oxygen tensions of lower altitudes and thus appropriate treatment is immediate removal to such altitudes. Because of the difficulties of transportation of severely ill patients in the circumstances normally prevailing on high mountains, removal should take place as soon as the diagnosis is suspected rather than when the patient is severely dyspnoeic. If oxygen is available, it should be given at high flow rates. Acetazolamide, a carbonic anhydrase inhibitor that acts as a diuretic and a respiratory stimulant, is a reasonably effective prophylactic against acute mountain sickness and may help to prevent pulmonary oedema [197–199]. However, the primary preventive measures are to take time over ascent, to return to lower altitude at night after climbing in the day, and to avoid taking people who have previously suffered from the condition on future expeditions.

### Near-drowning

Strictly speaking, drowning results from inhalation of water, although the terms 'dry drowning' and 'secondary drowning' are applied, respectively, to death due to

immersion without water inhalation (perhaps as a result of cold-induced vagal activity and apnoea) and to pulmonary oedema occurring up to 72 h after an immersion accident. In freshwater drowning, there is absorption of water from the lungs into blood, haemolysis and hyperkalaemic ventricular fibrillation. This is normally rapidly fatal, although occasionally, especially in children, drowning in freezing water may sufficiently suppress tissue oxygen demands as to be consistent with survival after immersion for as long as 30 min or more. Sea-water drowning results in diffusion of sodium, calcium and magnesium ions into the bloodstream, again leading to cardiac arrest.

In either type of drowning, prompt initiation of mouth-to-mouth respiration may result in the patient being resuscitated, although with freshwater drowning the chances of this are less. It has been advised, apparently paradoxically, that external cardiac massage should not be attempted if the victim is hypothermic, as recovery of temperature is accompanied by recovery of sinus rhythm while massage may provoke ventricular fibrillation [200]. If the victim is not obviously hypothermic, signs of cardiac arrest should be an indication for external massage. Resuscitated patients, as well as those who have inhaled water but who have not suffered arrest, should be admitted to hospital for correction of hypothermia and electrolyte abnormalities. If they become breathless and show falling oxygen tensions, secondary pulmonary oedema should be suspected and assisted respiration with PEEP instituted early [201,202]. The aetiology of this condition is not clear but may be related to removal of surfactant from the alveoli, with loss of waterproofing.

## Uraemia

Pulmonary oedema is a common accompaniment of chronic renal failure. Many factors may play a part in its aetiology; sodium and fluid retention leading to circulatory overload, protein loss with reduced plasma oncotic pressure and left ventricular failure may all contribute. There is almost certainly an element of increased permeability but the mechanism of this is unclear [203,204]. The clinical features of renal pulmonary oedema are similar to those of other forms of the disease, although care has to be exercised in distinguishing it from infections, pulmonary arteritis and reactions to drugs used in the treatment of the primary condition or for immunosuppression to enable transplantation [205]. The distribution of radiographic

changes is usually central rather than peripheral, and this may be helpful in making the distinction from the more typical peripheral pattern of oedema in shock lung.

## Lung re-expansion oedema

Occasionally the rapid relief of a pneumothorax may be followed by ipsilateral pulmonary oedema. The patient coughs and complains of shortness of breath, and blood gases may show hypoxaemia due to shunting of blood past unventilated alveoli [206]. Similar episodes may occur following the rapid drainage of a pleural effusion, and in these circumstances fatalities have been described [207,208]. Part of the explanation of these episodes may be the generation of excessively negative intrapleural pressures [209], although it is likely also that loss of surfactant in the collapsed lung makes the alveolar epithelium excessively liable to leak interstitial fluid [210].

Management of these episodes, all of which should be prevented by careful aspiration, depends on correcting hypoxaemia and allowing time for the oedema to resolve. In a very distressed or severely hypoxic patient, the condition could theoretically be alleviated by allowing the affected lung to collapse again, followed by cautious re-expansion.

## Pulmonary oedema in intravenous drug abusers

Intravenous drug abusers may develop pulmonary oedema following an overdose [211,212]. The patients are usually heroin addicts, although the syndrome may result from intravenous use of other drugs. The patient usually presents with typical signs of an overdose, cyanosed and with crackles in the lungs. Management is with oxygen, by respirator if necessary, and opiate antagonists. Recovery may occur, with clearing of the chest film, within 24–48 h if these measures are initiated sufficiently promptly. The condition is due to increased vascular permeability, possibly related to multiple small emboli of contaminants of the drugs. The diagnosis in such patients has become more complex with the increasing incidence of pulmonary complications of AIDS, as this is also not infrequently complicated terminally by diffuse pulmonary oedema.

## Pulmonary veno-occlusive disease

This is discussed in Chapter 26.

# BRONCHIECTASIS

DOUGLAS SEATON

## Definition

The definition of bronchiectasis is based on morbid anatomical appearances, the word being derived from Greek roots, *bronchion* meaning windpipe and *ektasis* a stretching out. Thus bronchiectasis is present when one or more bronchi are abnormally and permanently dilated. The condition was clearly described by Laënnec in 1819 after the postmortem examination of the lungs of an infant who died following whooping cough [1], and a popular textbook of the late nineteenth century stated correctly that bronchiectasis was 'not a separate disease but a result of various affections of the lungs and bronchi' [2], this sentiment being echoed today in that the morbid anatomical changes represent a common end-stage of a variety of pathological conditions.

## Prevalence

Since bronchiectasis has depended upon CT, bronchography or morbid anatomical examination of the lungs for certain diagnosis, no reliable figures are available for its prevalence in the population as a whole. As long ago as 1953, 1.3 cases of bronchiectasis per 1000 were reported in Bedford [3]; a similar prevalence of 1.5 cases per 1000 was found from the chest clinic follow-up of abnormal 'routine' miniature chest radiographs obtained from a sample of over 3.5 million examinations carried out in England and Wales in 1956 during the tuberculosis eradication campaign [4]. Despite the lack of subsequent data, it is common experience that a marked fall in the prevalence of bronchiectasis has occurred since that time. This decline is a consequence of the more effective treatment of childhood respiratory infections, including pneumonia, so that sharp falls in the numbers of children admitted to hospital with bronchiectasis coincided with the introduction of antibiotics [5,6]. Other important factors have been the introduction of effective vaccination programmes for whooping cough and measles, the decline in the prevalence of pulmonary tuberculosis and better social condi-

tions. Although such improvements in health are sometimes taken for granted in Western society, this is not the case in many developing countries where bronchiectasis remains a common problem [7]. Thus a large South African thoracic surgical centre serving a population of about 6 million was still carrying out 60–70 resections per year on patients with bronchiectasis in the 1980s [7], whereas most respiratory physicians in the West see only a few 'new cases' of bronchiectasis each year. Paradoxically, improved antimicrobial agents and other supportive care have allowed some patients, notably those with cystic fibrosis (CF), to survive into adult life despite gross bronchiectasis. These patients with CF, who account for approximately 1 in 2000 births and who would previously have died in childhood, now represent a significant number of repeated hospital admissions under the care of adult respiratory physicians. The accurate diagnosis of bronchiectasis depends upon high-resolution CT (HRCT), which can detect less severe forms of bronchiectasis that may easily be missed unless the physician pursues this possibility doggedly, so that the current prevalence of bronchiectasis is unknown.

## Aetiology and pathogenesis

Whereas most bronchiectasis is acquired during childhood, the condition may rarely result from a gross congenital developmental anomaly or be predisposed by some other inherited defect, be it ultrastructural (as in ciliary dyskinesia), related to a generalized defect of ion transport (as in CF) or due to an immunodeficiency syndrome (e.g. hypogammaglobulinaemia) (Table 28.1).

### Mucociliary clearance abnormalities predisposing to bronchiectasis

#### Genetically determined syndromes of ciliary dyskinesia

The recognition that abnormalities of ciliary function

**Table 28.1** Bronchiectasis: aetiology and pathogenesis (see text).

Pathogenic mechanisms	Aetiology
Primary infective insult	Bronchitis/bronchiolitis Pertussis Measles Adenovirus Pneumonia Tuberculosis
Primary impairment of mucous clearance	
Genetic, biochemical	Cystic fibrosis
Genetic, ultrastructural	Primary ciliary dyskinesias
Immunodeficiency syndromes, congenital and acquired	Common varied immunodeficiency Selective immunoglobulin deficiency Functional immune deficiency Secondary hypogammaglobulinaemia Human immunodeficiency virus infection
Hyperimmune response	Allergic bronchopulmonary mycoses
Infection secondary to bronchial obstruction	
Intraluminal	Slow-growing tumour, aspirated foreign body
Extraluminal	Lymphadenopathy
Miscellaneous inflammation	
Autoimmune disease	Inflammatory bowel disease Coeliac disease Systemic lupus erythematosus Rheumatoid disease Cryptogenic fibrosing alveolitis Primary biliary cirrhosis Thyroiditis Pernicious anaemia

might result in the development of bronchiectasis followed the observation that male infertility was sometimes associated with immotile spermatozoa [8,9]. A proportion of these patients gave a history of recurrent sinusitis and lower respiratory tract infection from early life and some were noted to have Kartagener's syndrome (chronic sinusitis, bronchiectasis and situs inversus, first described by Siewert and later by the Swiss paediatrician whose

name the syndrome bears) [9–13]. Electron microscope studies of the sperm tails in these infertile patients showed distinctive abnormalities [8,11] and because respiratory cilia normally have a similar ultrastructural composition, these were also examined under the electron microscope to see whether the associated respiratory disorder could be explained by a similar defect [12,14]. Such was indeed the case, the important defects being the absence of one or both rows of dynein arms in some patients and the absence of spoke heads or central sheaths in others [15]. These structures are illustrated diagrammatically in Fig. 1.13. The dynein arms are ATPase radial projections, two of which normally arise from each of nine pairs of microtubules that run longitudinally and which are arranged circumferentially around the cilia (or sperm tail). Ciliary bending is normally achieved by the outer of each pair of microtubules sliding over its inner partner in a coordinated fashion, the energy for this being provided by the dynein arms. This microtubular shortening is converted into a bending motion because the outer pairs of microtubules are tethered to each other and to the central sheath. Individual cilia share the same ultrastructural plane of symmetry and therefore normally work in concerted fashion to propel the mucus blanket in a cephalic direction. Such coordinated sliding and bending cannot occur (i) in the absence of dynein arms or radial spokes [16,17], (ii) in the presence of spatial transposition of microtubules [18] and (iii) in the presence of random ciliary orientation in which the cilia are anchored in disorganized fashion at the cell surface [19]. These abnormalities prevent normal transport of mucus from the bronchial tree to the mouth and result in serious impairment of the lungs' defence systems. More than one gene is thought to be responsible for these defects, and Kartagener's syndrome [20] has been considered to be a subgroup in a heterogeneous collection of disorders to which the terms *immotile cilia syndrome* [15,21] or *dyskinetic cilia syndrome* [22] have been applied.

The finding of dextrocardia in about half those patients of European origin with ciliary dyskinesia has been explained in terms of the dependence of embryological organ position on the presence of a uniform pattern of ciliary beating, the absence of which might result in random rotation of primitive organ precursors to either the left or the right. However, this hypothesis has been questioned as it does not hold for Polynesians with ciliary dyskinesia, in whom organ position is normal [23]. The immotile cilia syndrome (syn. primary ciliary dyskinesia [24]) is rare, with a prevalence of about 1 in 30 000, which is about twice that of the subcategory of Kartagener's syndrome. It is probably transmitted by an autosomal recessive gene with incomplete penetrance. Parents of affected children seldom have chronic respiratory symptoms but the chances of a sibling being similarly afflicted are about 25%.

### *Clinical features*

The clinical features are a result of impaired mucociliary clearance from the upper and lower respiratory tracts, the paranasal sinuses and the middle ear. Male infertility is also usually present, although this need not be the case where mucociliary transport is defective because of random ciliary orientation rather than immotility [19], so that men with primary ciliary dyskinesia should have seminal analysis before being told that they are infertile. Dextrocardia occurs in about half of cases in the absence of other congenital anomalies. Respiratory symptoms date from infancy or early childhood and include chronic rhinorrhoea and sinusitis. There may be otitis media and mild deafness. Cough is prominent and is indeed essential to compensate for the absence of normal mucociliary transport by shifting otherwise stagnant mucus. Recurrent lower respiratory tract infection may result in bronchiectasis, which is therefore acquired, because of delay in the removal of infected material from the bronchi [21].

### *Diagnosis*

The diagnosis should be considered in any patient with a history of recurrent upper and lower respiratory tract infection since childhood and can be regarded as established if (i) the features of Kartagener's syndrome are present, (ii) an adult male gives a consistent respiratory history and is found to have immotile live sperm or (iii) a woman or child gives a consistent respiratory history and has a sibling with Kartagener's syndrome or has consistent ultrastructural defects on a nasal or bronchial epithelial brush biopsy [15]. Impaired mucociliary clearance may be detected in adults by the presence of an abnormal saccharin test, in which the time is recorded for saccharin to be tasted in the mouth after a 0.5-mm particle has been deposited on the inferior turbinate in the nose. This usually takes about 30 min but times of up to 1 h may be normal. It is also possible to measure ciliary beat frequency with appropriate specialized video microscopy. The availability of facilities for electron microscopy of sperm tails and respiratory cilia may produce diagnostic confirmation, although even these may demonstrate no abnormality in some variants of primary ciliary dyskinesia [25]. Specimens of cilia for both video and electron microscopy may be obtained without local anaesthesia by running a bronchoscopic cytology brush along the mucosal surface of the inferior turbinate [26].

### **Other syndromes of ciliary dyskinesia**

#### *Young's syndrome (idiopathic obstructive azoospermia)*

Young [27] described a group of 52 infertile men in whom

poorly motile sperm were present in the epididymal tubes but not in the ejaculate. A history of severe chest disease in childhood followed by recurrent bronchitis was obtained in half of the cases and bronchiectasis is about one-fifth. Sinusitis may also be associated. Azoospermia in this syndrome may be caused by an functional obstruction to the flow of secretions in the vasa deferentia and the association between chronic paranasal sinusitis, lower respiratory tract disease and obstructive azoospermia may be due to a common defect of the ciliated columnar epithelium at these different sites. Although Young's syndrome has been proposed as a variant of the immotile cilia syndrome, the respiratory cilia in such patients appear for the most part to be ultrastructurally normal [28] and evidence regarding the nature of ciliary dysfunction is conflicting, since the abnormalities that have been reported could be a consequence rather than the cause of recurrent respiratory tract infection. Thus patients with bronchiectasis may be colonized by bacteria that may themselves produce ciliary toxins [29,30], so that the pathogenesis of the respiratory abnormalities in Young's syndrome is still unexplained [31,32]. Although the rheological properties of mucus in Young's syndrome may be abnormal, it is unlikely to be a *forme fruste* of CF because sweat electrolyte concentrations are normal [33,34]. The condition has not been found to be familial and situs inversus has not been associated. A history of mercury intoxication in childhood ('pink disease', caused by mercurous chloride in teething powders and vermifuges) was obtained in some patients who later developed Young's syndrome, so that this apparent association and the subsequent observation of a temporal decline in the incidence of this syndrome following the removal of such preparations from general availability raised further questions about possible cause and effect [35].

### *Cystic fibrosis*

CF is a relatively common hereditary disorder in which activity of a chloride channel known as the cystic fibrosis transmembrane conductance regulator (CFTR) is reduced according to the individual genetic mutation present. The incidence of CF is approximately 1 per 2000 live births. Although early symptoms are related to pancreatic insufficiency, patients who survive into childhood, adolescence and adult life classically develop persistent lower respiratory tract infection and as a result acquire widespread bronchiectasis, more than 90% of patients with CF dying of lung disease [36]. The lungs of patients with CF are virtually normal *in utero*, but once breathing commences the desiccated and viscid secretions resulting from the electrolyte transport defect impair mucociliary clearance so that trapped organisms lead to a cycle of persistent and increasing inflammatory load, ultimately resulting in the widespread bronchiectatic changes that characterize this

disease [37]. The diagnosis is made by finding the classic triad of pulmonary disease, pancreatic insufficiency and a raised sweat sodium concentration of 70 mmol/L or more, only 0.1% of patients with otherwise typical CF having normal sweat sodium and chloride concentrations below 50 mmol/L [38,39]. More than 90% of men with CF are azoospermic as a result of congenital bilateral absence of the vas deferens, a finding that may raise Young's syndrome in the differential diagnosis, this being characterized by bronchiectasis, sinusitis and infertility but not by pancreatic insufficiency, a raised sweat sodium concentration or the appropriate genetic typing found in CF. The condition is described fully in Chapter 30 and is not considered further here. It has been postulated that the presence of CFTR gene mutations (occurring in the absence of overt CF) may be responsible for some cases of bronchiectasis in the community [40].

### **Other conditions predisposing to bronchiectasis**

#### **$\alpha_1$ -Antitrypsin deficiency**

Hereditary homozygous  $\alpha_1$ -antitrypsin (syn.  $\alpha_1$ -protease inhibitor) deficiency occurs in about 1 per 4000 of the population and is well known for its association with panacinar and predominantly basal emphysema (see Chapter 23) and also with cirrhosis of the liver. The development of bronchiectasis, rather than emphysema, in adult life is less well known but has been reported in a few patients [41–45]. Thus some of the proteases released from phagocytes during pyogenic infection may be more liable to cause bronchial wall damage if unopposed by antiproteases, of which  $\alpha_1$ -antitrypsin is one.

#### **Inhalational injury**

There have been occasional reports of bronchiectasis developing as a consequence of the inhalation or aspiration of toxic or irritant substances, either in liquid form or when contained in smoke or fumes [46–48].

### **Developmental pulmonary anomalies**

#### ***Pulmonary agenesis***

Rare cases of 'congenital bronchiectasis' have been described in which most of the bronchi in a lobe or lung are found to be dilated. These cases present in childhood with symptoms and signs consistent with bronchiectasis. Following resection, the affected part of the lung shows no evidence of alveoli ever having developed beyond the bronchial abnormality [49]. This type of bronchiectasis may therefore be regarded as an example of partial pulmonary agenesis with a failure of peripheral parts of the lung to develop. Ipsilateral bronchiectasis has been found

in some patients who have presented in adult life with unilateral pulmonary artery agenesis [50].

#### ***Pulmonary sequestered segment***

Bronchiectasis may also occur congenitally within an intralobar sequestration (see Chapter 50) that contains disorganized, dilated and deformed bronchi [51]. These may communicate with normal surrounding lung tissue if the sequestration becomes complicated by infection and ruptures. The anomalous blood supply of sequestered segments may be demonstrated by aortography.

#### ***Tracheobronchomegaly (Mounier-Kuhn syndrome)***

This is also a rare condition, considered to be congenital, in which the cartilaginous rings of the trachea and its divisions as far as the segmental bronchi are enlarged, producing marked dilatation of the trachea and central bronchi [52]. The elastic and muscular tissues between the rings of cartilage are atrophic and may tend to bulge between the rings in the manner of tracheal diverticulae. These changes have the effect of causing the intrathoracic trachea and main bronchi to dilate during inspiration and to collapse on expiration. It is associated with chronic lower respiratory tract infection and bronchiectasis and tends to be diagnosed in the fourth or fifth decades when patients with this clinical presentation may be found to have transverse and sagittal tracheal diameters three standard deviations or more above the norm on the chest radiograph [53]. The more distal bronchial tree is not primarily affected. Characteristic bronchographic and CT findings have been described [53–55]. Associations with Ehlers-Danlos syndrome, cutis laxa and skeletal dysplasia have been recognized.

#### ***Williams-Campbell syndrome (bronchomalacia)***

This rare congenital syndrome is characterized by defective or completely absent bronchial wall cartilage, producing a mechanical abnormality that may contribute to the formation of bronchiectasis [56]. Symptoms of cough begin from infancy. The defect may extend from the fourth to the eighth generations of bronchi and CT shows a remarkable ballooning expansion of the proximal bronchi during inspiration, with collapse during expiration, these appearances having originally been demonstrated bronchographically [57]. Familial cases may occur in siblings, possibly as a result of an autosomal recessive mechanism of inheritance, although the disorder may also present sporadically [58,59].

It may be possible for other developmental bronchial anomalies to lead to the formation of bronchiectasis possibly as a result of secondary infection.

### Immunodeficiency syndromes

Apart from the anatomical and mechanical defences afforded by the epiglottis, the larynx, the act of coughing and mucociliary transport, the lung is also protected by bacteriostatic substances and by humoral and cellular immune mechanisms that may become defective for various reasons. Such defects sometime lead to recurrent or chronic lower respiratory tract infection, which may in turn be complicated by bronchiectasis.

Immunodeficiency syndromes are found in less than one-tenth of adult cases of bronchiectasis. Some of these are treatable with intravenous immunoglobulin replacement therapy [60,61], which may help to prevent increasing lung damage if started early enough. Thus it is advantageous to request serum levels of IgG, IgA and IgM and also IgG subclasses in patients in whom bronchiectasis is suspected or evident, particularly when these patients present at a younger age or when recurrent infection dates back to early life. Such a diagnosis may be more likely where there has been no single triggering antecedent pneumonic episode. The humoral immunodeficiencies include (i) congenital X-linked (Bruton's) agammaglobulinaemia, producing infection in infancy once maternal IgG is exhausted, and (ii) the acquired form of common varied immunodeficiency (CVID; syn. common variable hypogammaglobulinaemia).

CVID is the most common of these defects, presenting at any age but with a peak incidence in childhood and adolescence, and is associated with chronic sinusitis and repeated episodes of infective bronchitis leading to bronchiectasis in adult life. The levels of immunoglobulins found are rather variable: IgG is often reduced to less than 2 g/L and IgA is often virtually undetectable; IgM may be reduced to less than 0.2 g/L but this need not be the case and normal levels may be found.

Other defects that may be associated with bronchiectasis include selective IgG subclass deficiencies that may be found in the presence of a normal total IgG level [62–66]. Not all IgG subclass deficiencies are clinically relevant and sometimes one subclass defect may be compensated for by the others. Bronchiectasis is not usually associated with isolated IgA or IgM deficiencies but is more likely if these occur in association with selective IgG subclass deficiencies (e.g. IgG<sub>2</sub> and IgA). Selective IgA deficiency [67] is quite common in people of European stock and leads to recurrent upper respiratory tract infection in only a small minority of those with the defect. Primary selective IgM deficiency is very rare and is more likely to be a consequence of lymphoma. Selective IgE deficiency appears to be of no consequence.

Functional immunoglobulin deficiencies should be considered in patients who have recurrent respiratory infections but in whom the neutrophil and lymphocyte counts are normal and who also have normal immunoglobulin

and complement levels. These patients fail to produce antibodies in response to a specific challenge and may sometimes be detected immunologically by their failure to produce a measureable serological response to pneumococcal vaccine and tetanus toxoid [68].

Immunity may also be impaired by both neutrophil and, less frequently, by T-cell dysfunction. Bronchiectasis has also been associated with a natural killer cell dysfunction in which lymphocytes do not express human leucocyte antigen (HLA) class I antigen on their surface, the so-called 'bare lymphocyte syndrome' [69].

Thus there are many different types of quantitative or functional immune deficiency [70–75] that reduce the capacity of the lungs to deal with pyogenic infection and some of these may lead to bronchiectasis. Impaired immunity with secondary hypogammaglobulinaemia may also result from coexisting disease, particularly malignancy such as lymphoma, chronic lymphatic leukaemia and myeloma, as well as from other non-neoplastic diseases with heavy protein (and therefore antibody) losses such as the nephrotic syndrome and protein-losing enteropathy [61].

For a detailed description of lung defences and immunology, the reader is referred to Chapter 4.

### Infection in the pathogenesis of bronchiectasis

Although the pathogenesis of bronchiectasis remains the subject of speculation and debate, it is probable, other than in rare congenital forms, that infection plays a fundamental role in both the initiation of the morbid anatomical defect and the perpetuation of the symptoms of bronchiectasis.

Many cases of bronchiectasis originate from a lower respiratory tract insult in early childhood, the patient often having been 'chesty' for as long as can be remembered. A remote history of childhood 'pneumonia', whooping cough, a bad attack of measles or tuberculosis may be cited by the patient, although in somewhat less than half of all cases such an event cannot be recalled. Thus a series of 116 cases from Edinburgh reported a history of pneumonia in 28%, pertussis in 10%, bronchitis/bronchiolitis in 5%, tuberculosis in 5%, measles in 3% and other causes in 5%, leaving the cause 'undetermined' in 44% [76]. One North American series obtained a history of pneumonia as the first known respiratory incident in two-thirds of cases [77], while a series of 187 children attributed the disease to infection in almost 70% of cases, the remainder being divided evenly between congenital abnormalities and aspiration [6]. A more recent North American study of 123 patients with proven bronchiectasis, half of whom had never smoked, found 'pneumonia' to be the most common antecedent event, this having been supposed to have occurred in 35% of cases; about 7% had been accounted for by whooping cough, 10% by 'granulomatous disease'

(including tuberculosis and sarcoidosis), 4% by genetic disorders (comprising CF,  $\alpha_1$ -antitrypsin deficiency and syndromes of ciliary dyskinesia) and 14% by miscellaneous disorders. No antecedent lung injury could be identified in 30% of cases [78].

### **Pertussis (whooping cough)**

Whooping cough (discussed in Chapter 12) has long been associated with bronchiectasis; indeed Laënnec believed it to be the commonest cause [1]. Nowadays in many Western countries the prevalence of pertussis has been reduced but the disease has by no means been eradicated and it continues to occur in unvaccinated individuals. It produces a necrotizing bronchitis, and associated endobronchial mucus and debris commonly cause small peripheral areas of atelectasis, radiographic evidence of these being found in over 40% of 150 consecutive childhood cases in one early series [79]. Such shadowing is usually short-lived and bronchiectasis probably only occurs in a small proportion of these patients, some of whom may first develop a secondary bacterial pneumonia.

### **Measles**

Measles may also be accompanied by severe inflammation of the bronchial wall and pneumonia is its most important complication. Measles was implicated in 14% of a series of patients with bronchiectasis from North Carolina in 1978 [77]. As with whooping cough, the prevalence of measles has fallen in the West following the introduction of vaccination (see Chapter 12), although this illness remains a common cause of morbidity and death among poorer people in developing countries. In Cape Town, South Africa, Kaschula and colleagues [80] reported 57 new cases of bronchiectasis in children, a strong causal link with measles being evident in 20 of them. These same workers reported the postmortem findings of 21 children who had died in the wake of measles. The majority had evidence of superimposed adenovirus or herpes simplex pneumonia that was associated with a severe bronchiolitis and bronchitis, leading the authors to speculate that the occurrence of these infections in children shortly after measles may be an important factor in the development of bronchiectasis [80,81]. A similar association between measles, adenovirus infection and bronchiectasis has been reported by others [82].

### **Adenovirus**

Adenoviruses alone account for about 5% of respiratory infections in children, some serotypes (e.g. 1, 3, 4, 7 and 21) being more virulent than others. A longitudinal study of 22 children who had adenovirus type 7 pneumonia showed

that over one-quarter of them had evidence of bronchiectasis at 10-year follow-up [83].

### **Mycobacteria**

Although 'postprimary' pulmonary tuberculosis almost always produced bronchographically demonstrable bronchiectasis [84,85], such morphological distortion seldom produces the clinical symptoms classically associated with bronchiectasis. The explanation for this is that the tuberculous process tends to selectively affect the upper lobes, from which secretions are able to drain with the aid of gravity, whereas other infections often involve dependent parts of the lungs from which unassisted drainage is poor so that sepsis persists. The initial tuberculous infection that produces a 'primary complex' may in some cases result in residual bronchiectasis when the infiltrate involves the middle or lower lobes. The relatively narrow middle lobe bronchus has long been known to be vulnerable to obstruction, including compression by enlarged hilar glands, sometimes producing the so-called 'middle lobe syndrome', with a variety of findings ranging from recurrent middle lobe pneumonia to atelectasis and bronchiectasis [86,87]. However, any associated bronchial wall infection and necrosis may play a summative role in the pathogenesis of postprimary tuberculous bronchiectasis [88].

Opportunistic mycobacterial infection may also be associated with bronchiectasis in immunocompetent patients. The organisms that have been implicated include not only *Mycobacterium avium-intracellulare* and *M. kansasii* but also occasionally so-called 'rapid growers' such as *M. fortuitum* and *M. chelonae* [89–92]. The usual radiographic findings are indistinguishable from tuberculosis, with a fibronodular infiltrate affecting the upper lobes, although occasionally a more specific CT appearance may be evident with scattered small nodules that may be associated with bronchiectasis [90,93,94]. In all probability, these 'atypical' mycobacteria are usually secondary colonists, although it has been suggested that the underlying bronchiectasis may progress more rapidly in patients from whom these organisms are persistently recovered [95].

### **Pneumonia**

When pneumonia precedes bronchiectasis, the acute event has often occurred in childhood and is poorly documented or half-forgotten as implied above [76–78]. The pneumonic episode may follow on the heels of an epidemic childhood infection such as whooping cough, measles, adenovirus or other infection. Bacterial pneumonic infections are much more likely to be controlled as a result of the widespread availability of antibiotics in countries with well-developed health services, tending to remain uncomplicated by so-called 'old-fashioned

bronchiectasis'. This is not the case in most parts of the world where health resources are scarce and patchily spread, so that if the patient survives suppurative pneumonia is more likely to be followed by bronchiectasis. Although no detailed prevalence data exist, such complicated infection, which may occur in adult life as well as in childhood, has been recorded as a major problem in South Africa where developed Western medical and surgical facilities abut large and relatively poor communities [7].

Bronchiectasis may occasionally be acquired in adult life following pneumonia caused by organisms seldom associated with suppurative complications such as *Mycoplasma pneumoniae* [96–98].

### Human immunodeficiency virus

Although often first brought to clinical light by an episode of *Pneumocystis carinii* pneumonia, human immunodeficiency virus infection is increasingly recognized as a predisposing factor for repeated infection by other more common respiratory pathogens, such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, *Staphylococcus aureus* and *Pseudomonas aeruginosa* particularly in patients with less severe immunological impairment [99]; such repeated infections may lead to bronchiectasis [100,101]. This does not represent a major clinical problem at present but it is possible that it could become one if prophylaxis and treatment of major infective episodes prolongs survival sufficiently to produce a cohort in whom the pathology has had time to develop [102].

**Fig. 28.1** Loss of volume in plugged acini results in traction on more proximal bronchi that then become dilated. (a) Terminal bronchioles subtending acini (primary lobules) are obstructed by secretions. (b) Air is absorbed from the acini which collapse, creating increased negative pressure on the bronchi. (c) The bronchi dilate into saccules. (Modified from Coope [105] with permission.)

### Obstruction in the pathogenesis of bronchiectasis

Obstruction to a part of the bronchial tree by itself is unlikely to cause bronchiectasis unless there is accompanying infection. Thus experiments in which the bronchi of rabbits and rats were ligated led to the conclusion that bronchiectasis in rabbits only occurred if the sterility of the preparation was spoiled, whereas rats, which possess a resident bronchial flora, developed infection followed by bronchiectasis [103,104]. Undoubtedly obstruction in any viscus in humans results in stasis, which then predisposes to infection. In the lungs of humans, bronchiectasis may result from (i) the obstruction of many small peripheral bronchi or (ii) the obstruction of a more central bronchus.

Obstruction of small peripheral bronchi is a feature of lower respiratory tract infection in children, notably in whooping cough [79], where mucus and inflammatory debris are shed into the lumina of peripheral bronchi, which because of their small diameters are more readily obstructed than is the case in adults. As a consequence of this, radiographic evidence of patchy areas of atelectasis is common in whooping cough [79]. Whether such atelectasis plays an important causal role in the development of bronchiectasis is unknown but it has certainly been proposed as a factor (Fig. 28.1). It is also possible that the epithelial disruption produced by whooping cough, or other primary infections such as measles, paves the way for more persistent lower respiratory tract infection by impairing the primary defences of the lungs.

Proximal and prolonged more central bronchial obstruction may result from (i) an intraluminal occlusion as may occur with a slow-growing tumour such as a carcinoid or sometimes with rare slow-growing benign tumours (e.g. lipoma, papilloma, fibroma, chondroma) [106–108] or with an aspirated solid foreign body, or (ii) extramural compression due to mediastinal or other masses or, in the case of children, whose bronchi are soft and more compressible, by enlarged hilar glands. The

middle lobe bronchus is especially susceptible to occlusion because of its relatively small lumen and its emergence from the intermediate bronchus at a right angle, at which point it is surrounded by lymph nodes that if enlarged tend to compress it. This produces the so-called middle lobe syndrome [86,87], in which the lung subtended by the obstructed middle lobe bronchus may become partially or completely atelectatic. This is also sometimes referred to as Brock's syndrome after the author of the original description, in which tuberculosis was put forward as the cause [109]. With the superimposition of infection, an inflammatory exudate is produced and the bronchial walls themselves become inflamed and weakened with the development of bronchiectasis.

Bronchiectasis resulting from the aspiration of a foreign body may occur in both adults and children [110–112]. The right side is affected more often than the left, usually the lower lobe or posterior segment of the upper lobe. Le Roux and colleagues [7] reported foreign body aspiration as the cause of bronchiectasis in 5.6% of 1003 resections carried out for this condition in a South African population. In series appertaining to Western populations, the proportion is in the order of 1% overall, but is higher in children. Frequently no history of the event itself is obtained and many months or even years may elapse before the diagnosis is made [113,114]. The site of retention of a foreign body is often sufficiently proximal for it to be viewed bronchoscopically. However, this is not always the case and the flowering heads (inflorescences) of timothy grass and other plants tend to move peripherally [112,115], in much the same way as they may migrate up the sleeve of a playing child.

### **Inflammation in the pathogenesis of bronchiectasis**

The foregoing sections have considered the association of certain forms of pulmonary infection and bronchial obstruction with the later development of bronchiectasis. This section considers in more general terms the ways in which chronic inflammation in the lower respiratory tract, once started, may cause progressive local damage, resulting in permanent dilatation of the affected bronchi.

The most common means by which such inflammation becomes established is infection. Any infecting organisms first have to overcome the lungs' primary defences in order to establish themselves. These defences include impaction on the mucous layer overlying the bronchial epithelium and clearance by a combination of normal respiratory ciliary function and coughing. Some organisms, such as *H. influenzae*, *Strep. pneumoniae* and *Ps. aeruginosa*, may themselves elaborate substances that have the capacity to impair normal ciliary movement and in doing so may reduce the capacity of the lungs to rid themselves of the infection [116–120].

Additional defence mechanisms include local cellular and immune responses, including the elaboration of antibodies. One crucial cellular response involves the migration of neutrophil leucocytes from the pulmonary capillary circulation across endothelium, interstitial tissue and respiratory epithelium in order to reach the bronchial lumen. These neutrophils mount an inflammatory response intended to assist in the phagocytosis and elimination of infecting organisms. However, when such elimination is not achieved and significant numbers of organisms become established as 'colonists' rather than behaving as ephemeral 'raiding parties', the host reacts with a persistent attempt to contain the infection, so that the inflammatory response becomes chronic, with the continuous elaboration of potentially harmful substances, including damaging free radicals and neutrophil elastase [121,122]. In keeping with this, the mucopurulent sputum of patients known to have bronchiectasis has been shown to contain elastase [123]. Elastase activity is also found in the sputum of patients with chronic bronchitis, but only during exacerbations and not when the sputum is mucoid [124]. Elastase has similarly been shown to clear from the mucopurulent sputum of patients with bronchiectasis should their sputum become mucoid following treatment with antibiotics [125]. Neutrophil elastase has the potential to attack elastin in the bronchial walls so that they may become weakened and subsequently dilated as a result of the elastic forces of the surrounding lung. Elastase also has the potential to disrupt ciliary action [126,127] and results in increased production of mucus in the lungs [128], as well as destroying important opsonins and seriously impairing the host's defences against pseudomonal colonization [129].

The cell-mediated immunological component of the process occurring in the bronchial walls is characterized by the presence of mainly T lymphocytes [130], with interleukins and other proinflammatory cytokines also being produced [131]. It has also been shown that the ratio of sputum to serum albumin is raised in these patients, implying increased protein transudation from the blood to the airways in the presence of inflammation [132], and that this ratio also falls following antibiotic treatment in patients with bronchiectasis [125].

It is therefore possible to hypothesize that the inflammatory process incited by certain infective organisms in the lungs tends to perpetuate infection by impairing clearance mechanisms and that this results in a vicious circle of increasing inflammatory damage to parts of the bronchial tree in the process; furthermore, this process is important in producing the gross pathological changes characteristic of bronchiectasis [133,134].

### **Immunological changes**

The presence of chronic lower respiratory tract infection

such as may occur in bronchiectasis is associated with measurable immunological abnormalities. Raised levels of IgG, IgA and IgM are common and have been reported in the literature [66,74]. Such raised levels have not been found in control groups comprising patients with asthma and chronic bronchitis [74] but in bronchiectasis have been found to correlate with the severity of disease. It has been postulated that they are a response to the persistent antigenic stimulation resulting from chronic infection in the bronchial tree and that the presence of bronchiectasis itself evokes a hyperimmune response.

The presence of rheumatoid factor was found in 52% of one series of 53 patients with bronchiectasis [74]. This finding is non-specific, since the presence of rheumatoid factor has been found with greater than expected frequency in many chronic pulmonary diseases as well as in other non-respiratory disease both acute and chronic, rheumatoid and non-rheumatoid. The production of rheumatoid factor can in these situations be regarded as a response to a wide variety of antigenic stimuli that may come from the products of infection or from those elaborated in the process of tissue destruction.

Antinuclear antibodies are also present in 10–28% of patients with bronchiectasis or 'chronically infected bronchitis' [74,134–136]. These antibodies have not been shown to have a causal role in the tissue damage associated with bronchiectasis and their presence may also be an epiphenomenon. Other antibodies against smooth muscle, thyroid and gastric parietal cells are found but are less common.

Immune complexes may be detectable in the circulation of patients with bronchiectasis [137] and have been taken to be indicative of a normal antibody response to the heavy antigenic level sustained by patients with the chronic pulmonary suppuration that may be found in bronchiectasis. However, such immune complexes have been causally associated with cutaneous vasculitis in a few patients with severe bronchiectasis, possibly occurring in response to circulating endotoxins [138]. Cutaneous vasculitis may also rarely occur in CF-associated bronchiectasis [139].

### Autoimmune disease

Autoimmune diseases are more frequently associated with bronchiectasis than would be expected to occur by chance. These include inflammatory bowel disease, particularly ulcerative colitis, coeliac disease, primary biliary cirrhosis, rheumatoid arthritis, systemic lupus erythematosus, thyroiditis and pernicious anaemia [66,140–143]. Similar associations have been noted in cryptogenic fibrosing alveolitis [144]. The mechanisms by which autoimmune diseases develop in human are unknown. Allison and colleagues [145] postulated a lymphocyte-mediated defect resulting in a failure to recognize

'self', with the consequent production of antibodies against a range of normal tissue components, including mucosal surfaces. Speculation surrounds the possibility that immune complexes may have pathogenic effects on the lungs in bronchiectasis and in other associated autoimmune diseases [138,146].

An association between chronic productive cough (with or without bronchiectasis) and inflammatory bowel disease was initially reported in 1976 [142]. Butland and colleagues [141] laid further emphasis on the particular connection between ulcerative colitis and bronchiectasis when they reported seven cases in 1981. The chronic productive cough postdates the symptoms of colitis in nearly all cases, not uncommonly by months or years, and the occurrence of quite florid bronchiectasis after the bulk of inflammatory disease has been removed by total colectomy is well recognized although not satisfactorily explained. In such patients, large numbers of neutrophils have been found in fluid recovered by bronchoalveolar lavage, as well as in some samples of lung tissue, suggesting that these cells play a role in the inflammatory processes responsible for the lung lesions [143]. There are also reports of apparent symptomatic benefit when the respiratory symptoms are treated with systemic corticosteroids, an intervention that would be avoided instinctively in cases of chronic suppurative lung disease [141,143].

A probable association between bronchiectasis and rheumatoid disease has been reported [147,148]; indeed bronchiectasis was found to be 10 times more common in patients with rheumatoid rather than those with osteoarthritis [149]. It has also been suggested that bronchiectasis is found with the same frequency as pulmonary fibrosis in rheumatoid arthritis [147]. However, the latter condition is considered to be an extra-articular manifestation of rheumatoid disease, whereas it is speculated that bronchiectasis is more likely to result from a predisposition to lower respiratory tract infection as a consequence of either rheumatoid disease or its treatment [148]. Certain HLA variants have been shown to be more common in patients with rheumatoid arthritis and bronchiectasis together than in those with rheumatoid arthritis alone [150]. Some series have indicated that when bronchiectasis does occur it usually precedes rheumatoid arthritis [148], whereas others have implied that this is more often not the case [151,152]. Most patients have seropositive disease and those in whom the respiratory symptoms come first may have milder arthritis [151]. Seronegative arthritis that has been regarded as 'reactive' has been observed to remit when the lower respiratory tract infection associated with bronchiectasis is brought under control [153]. Xerophthalmia has been found to be more common in patients with rheumatoid arthritis and bronchiectasis than it is in rheumatoid arthritis alone [148].

Sjögren's syndrome may occur in primary form with keratoconjunctivitis sicca and xerostoma alone or in association with a connective tissue disease, commonly rheumatoid arthritis. High titres of anti-Ro and anti-La antibodies in the serum are characteristic. There may be associated atrophy of tracheobronchial submucous glands, leading to dryness with chronic cough and a tendency to develop recurrent lower respiratory infection and bronchiectasis [154].

Bronchiectasis has been reported in association with lung, heart–lung and bone marrow transplantation, possibly occurring as a more proximal airway manifestation of the obliterative bronchiolitis (syn. bronchiolitis obliterans) that is a usual finding in chronic rejection or graft versus host disease [155,156].

### Atopy and asthma

Comparisons of patients who have bronchiectasis with control subjects have shown no significant difference in the prevalence of atopy between the two groups in terms of the presence or absence of positive skin-prick tests to common allergens or with regard to relative serum IgE concentrations [66,157]. This is in contrast to patients with CF in whom atopy may be more common [158]. One study from Hong Kong found a higher prevalence of asthma (in the absence of evidence of allergic bronchopulmonary aspergillosis) in ethnic Chinese patients with diffuse or localized bronchiectasis [159], whereas another found the bronchiectatic group displayed greater bronchial hyperreactivity to histamine and methacholine than controls, although whether this had any pathogenic significance was, and still is, unclear [157].

### Allergic bronchopulmonary mycoses

Allergic bronchopulmonary aspergillosis (ABPA) has long been recognized as an occasional cause of bronchiectasis [160]. Atopic subjects, who also usually have asthma, are affected by this condition which arises as a result of allergy to *Aspergillus* spp., *A. fumigatus* being the fungus most frequently implicated. These patients typically have 'fleeting infiltrates' on their chest radiographs (or rounded opacities in the case of 'muroid impaction'; see below), a positive immediate skin-prick test to *A. fumigatus*, a peripheral blood eosinophilia and a raised serum level of IgE, this tending to reflect the level of activity of the allergic process. *Aspergillus* precipitins [144] are detectable in about 60% of typical cases. The fleeting shadows may clear spontaneously or with systemic corticosteroid treatment. The pathology shows an alveolar eosinophilic infiltrate. Additionally such patients may develop plugs of intra-bronchial mucus, containing eosinophils and sometimes fungal mycelia. These may result in bronchial obstruction

(or muroid impaction), producing various radiographic features that include rounded opacities (Fig. 28.2) and segmental, lobar or rarely whole lung atelectasis. These plugs of mucus (which are sometimes coughed up) are also associated with inflammatory changes in the bronchial wall that may result in permanent damage, demonstrable radiographically as proximal bronchiectasis in which relatively normal small bronchial and bronchiolar filling may be seen beyond grossly dilated proximal bronchi [160] (Fig. 28.3). The pathogenesis is probably a prolonged asthmatic late-phase reaction in response to persistent pulmonary *Aspergillus* antigenic stimulation. The upper lobes of the lungs are most likely to be affected by ABPA-associated bronchiectasis for reasons that are unclear, but in practical terms means that these patients are less likely to have trouble due to stagnant secretions than patients with other forms of bronchiectasis that typically affect the dependent parts of the lungs. Advanced cases of ABPA may develop considerable pulmonary fibrosis with loss of lung volume [161,162]. *A. fumigatus* commonly colonizes patients with CF and 10–15% of these patients go on to develop ABPA, which may result in further respiratory impairment [163]. A survey of 50 patients with 'idiopathic' bronchiectasis confirmed bronchographically found that 10% of cases had evidence of sensitization to *A. fumigatus* that was previously unsuspected and had been overlooked [164]. ABPA is described in detail in Chapter 21.

Fungi other than *Aspergillus* may cause allergic bronchopulmonary mycoses that produce clinical syndromes very similar to ABPA and these probably account for cases in routine clinical practice in which serological or skin-prick test evidence of *Aspergillus* infection cannot be demonstrated [165–168]. It is likely that some allergic mycoses other than ABPA may cause bronchiectasis but evidence is so far lacking.

### Other associated conditions

A variety of rare conditions have been associated with bronchiectasis. These include the yellow nail syndrome, comprising a triad of yellow, thickened, dystrophic finger-nails, chronic dependent lymphoedema and pleural effusions [169]. This condition, which may result from hypoplastic peripheral and pleural lymphatics, has also been associated with other respiratory abnormalities including sinusitis, recurrent pulmonary infections and bronchiectasis. Various immunological abnormalities have also been described in individual patients with the yellow nail syndrome, including lymphopenia, hypogammaglobulinaemia, reduced circulating levels of IgA and of B cells [170]. There are isolated reports of bronchiectasis occurring in association with Klinefelter's syndrome [171] and dyskeratosis congenita [172].

**Fig. 28.3** High resolution CT showing proximal bronchiectasis predominantly affecting the upper zones of the lungs of a 71-year-old woman with asthma complicated by allergic bronchopulmonary aspergillosis.

### Mechanisms by which the bronchi may dilate

Many explanations for the dilatation of the bronchi in bronchiectasis have been advanced, no single explanation being entirely satisfactory, so that it is probable that various mechanisms interact according to the primary pathology in order to produce a common end-result.

### Atelectasis theory

It was shown experimentally over 60 years ago that the aspiration of viscid material into peripheral parts of the bronchial tree may result in atelectasis and dilatation of the bronchi in the collapsed area [173]. Such dilatation is compensatory and occurs because atelectasis, in reducing lung volume, increases intrapulmonary negative pressure. This in turn dilates any bronchi proximal to the block, as these remain in communication with the atmosphere (see Fig. 28.1). Lander [174] subsequently concluded that three possible events might follow.

1 The collapsed part of lung might re-expand, with the disappearance of the compensatory bronchial dilatation. Such 'reversible bronchiectasis' is well recognized and is a reason not to diagnose bronchiectasis on the basis of the CT finding of bronchial dilatation when this is associated with apparent consolidation of surrounding lung after a recent pneumonic episode.

2 The lung collapse and consequently the associated bronchial dilatation may become permanent.

3 The collapsed portion of lung may re-expand but the bronchi remain dilated because of damage to their walls by an infective (or other inflammatory) process.

### Pressure of secretions theory

This states that following the plugging of a bronchus with mucus or other material, secretions distal to the obstruction accumulate and mechanically distend the bronchi beyond the block [175]. This mechanism has already been mentioned and would seem to be experimentally tenable only in the presence of bronchial wall inflammation such as might occur as part of an infective process [103].

### Traction theory

This states that bronchial dilatation occurs secondarily to fibrosis of lung parenchyma, the resulting scar tissue requiring high inflation pressures on inspiration to overcome abnormally high retractive forces. This mechanism would clearly not account for cases of bronchiectasis with little lung parenchymal fibrosis but does accord with the occasional pathological finding of bronchiectasis in cases of extensive pulmonary fibrosis ascribed to a variety of conditions, including radiotherapy, rheumatoid disease, scleroderma and cryptogenic fibrosing alveolitis [176].

It should be noted that with the possible exception of the traction theory, all other mechanisms require a weakening of the bronchial wall and, excepting rare congenital abnormalities such as bronchomalacia, this requirement is likely to be satisfied only as a result of the presence of inflammation. It is probable that inflammation usually results from infection, although other non-infectious inflammatory processes such as sarcoidosis [177] or allergic bronchopulmonary aspergillosis (see Chapter 21) may be responsible in a minority of cases. Once the morphological changes that constitute bronchiectasis have been instituted, then a vicious circle of secondary infection resulting in further lung damage may occur [134,178].

### Pathology

General pathological features in bronchiectatic lungs include the dilatation of medium-sized subsegmental bronchi from about the fourth to the ninth generations. The bronchiectatic areas may become lined by squamous or columnar epithelium frequently denuded of cilia; indeed there may be no recognizable epithelial lining at all on the surface of involved bronchi. Depending upon the severity of the process, inflammation of the walls of the bronchi results in a variable degree of atrophy, with destruction of muscle and elastic components, these being replaced by fibrous tissue so that sometimes little muscle or cartilage remains. The walls of the bronchi may be infiltrated by polymorphonuclear neutrophils, which are also found in the bronchial lumen. A dense intramural lymphoid infiltrate is common in certain cases (see below). According to the extent of disease, small side-branching bronchi and bronchioles may be cut off from their parent,

to be obliterated and lost as a result of the inflammatory process [179]. Reid [180] claimed that this destruction was more important from a functional standpoint than bronchial dilatation and suggested that the term 'bronchitis obliterans' might therefore be preferable to bronchiectasis, a terminological change that has not been adopted by clinicians or pathologists whose conceptions of bronchiectasis are firmly rooted.

Less severe bronchial deformities take the form of cylindrical (syn. fusiform or tubular) dilatation, whereas gross changes may be saccular (syn. cystic). Such saccular bronchiectasis in which dilatation is greatest in the more distal parts of affected bronchi may be clearly seen with the naked eye (Fig. 28.4), the saccules being in continuity with the bronchi [181]. Their walls are thin and composed of fibrous or granulation tissue sometimes lined by metaplastic squamous epithelium that is often ulcerated.

The affected airways may contain an exudate of mucopus, and in saccular bronchiectasis the saccules themselves may be filled with pus. The presence of such material indicates that infection is active. When there is no infection, there is minimal exudation and the condition may be termed 'dry bronchiectasis', whereas if hypersecretion of mucus continues as a result of chronic infection the condition is termed 'wet bronchiectasis', the symptoms of which may be indistinguishable from purulent chronic bronchitis [180] except that ordinarily the volume of mucopus is greater in bronchiectasis.

Fig. 28.4 Gross cystic bronchiectasis in the lower lobe of excised left lung.

Peribronchial fibrosis is common and the surrounding lung may also contain a variable amount of fibrosis, atelectasis and pneumonia.

The vascular supply to affected areas is altered, with the loss of much of the alveolar capillary bed as a consequence of destructive inflammation and scarring. This results in the opening up of precapillary anastomoses between large hypertrophied bronchial arterial branches, containing blood at systemic pressure, and the pulmonary arterial circulation [182,183]. The loss of this capillary bed and the presence of systemic-to-pulmonary shunting [184] may contribute to the development of pulmonary hypertension, with subsequent cor pulmonale that may complicate extensive hypoxaemic bronchiectasis.

### Site of bronchiectasis

A preponderance of bronchiectasis on the left side and in the lower lobes has been noted by many authors [7,49,185]. The upper lobes are affected least frequently and the middle lobe and lingula occupy an intermediate position with regard to frequency of involvement, as might be expected from their topographical position. When the left lower lobe is involved it is common for the lingula to be affected as well. One series of 215 bronchographically demonstrated cases found unilateral involvement in 65% of patients [185], a figure in close agreement with Spencer's review of three series comprising 322 cases in whom unilateral disease was found in 66% [49]. A breakdown of the 215 cases referred to above revealed disease confined to one lobe only in 31%, to more than one lobe unilaterally in 34%, and bilateral involvement in 35% [185].

### Classification

Pathological classifications of bronchiectasis have been based on the thesis of Francis Whitwell [49,181,186]. This work incorporated the microscopic examination of 180 surgical lobe or whole-lung specimens obtained in Liverpool between 1946 and 1948, before the general availability and use of antibiotics. Very few patients in this series were aged over 40 years. Of these cases, 18% were thought to be of congenital origin, characterized by the presence of large dilated bronchial sacs throughout the involved lobe or lung, with no microscopic evidence that more distal bronchiolar or acinar structures ever developed; 44% fell into no particular category and the remaining 87 patients (48%) were allotted to three morphologically distinct groups: follicular, saccular and atelectatic.

#### Follicular bronchiectasis

This type acquired its name from the presence of numerous lymphoid follicles situated in thickened, usually

cylindrically dilated bronchial walls. Enlarged hilar glands were noted to be a feature. The majority of specimens were obtained from patients aged 5–15 years [181]. Over half of 28 patients in whom records were available had been symptomatic from infancy.

#### Saccular bronchiectasis

This was characterized by the presence of macroscopically visible thin-walled, saccular (sometimes called cystic) bronchial dilatations. No patients in this group were aged under 15 years at operation and of 16 in whom clinical records were available, 70% became symptomatic between the ages of 13 and 25 years.

#### Atelectatic bronchiectasis

As the name implies, this form was associated with some pulmonary collapse. It was predominantly right-sided in contrast with follicular and saccular bronchiectasis, which involved the left lung more commonly. The right middle lobe was frequently involved and a number of specimens showed evidence of tuberculosis, suggesting that some of these cases resulted from proximal bronchial obstruction by enlarged hilar glands, to which the rather slender right middle lobe bronchus is particularly susceptible [86,87,109]. Most of these patients were submitted to surgery between the ages of 5 and 10 years, although a few patients up to the age of 30 years were included.

From the relatively few clinical records available in this series (59), it was concluded that all three groups were associated with pneumonia but a relationship with whooping cough or measles was only found in the follicular and atelectatic groups. The association between measles and follicular bronchiectasis is supported by more recent clinicopathological work from South Africa [80].

### Clinical features

Bronchiectasis may produce no symptoms and physical signs may be entirely absent [187,188], as has been shown in the past by the finding of typical bronchographic appearances following the investigation of a plain chest radiographic abnormality on a 'routine' film. At the other end of the clinical scale, it may produce a persistent cough productive of distressingly copious volumes of mucopurulent and sometimes fetid sputum, in a breathless and chronically disabled patient. Most cases belonging to the first category go fittingly undiagnosed for obvious reasons and those from the second are fortunately becoming increasingly uncommon [62,189,190], at least in countries that possess readily available antibiotics and facilities for immunization against measles and whooping cough. The majority of cases encountered nowadays in developed countries fall between these two extremes. Not uncommonly

monly the onset of symptoms may date back to childhood and an episode of severe whooping cough, measles or 'pneumonia' may be recalled by the patients or their relations.

### Symptoms

Cough is the most common symptom of bronchiectasis. It is usually persistent and productive of mucopurulent sputum but may be intermittent with 'dry' periods. As bronchiectasis involving the more dependent parts of the lungs progresses, sputum production often becomes more continuous, voluminous and purulent. Patients with such 'wet' bronchiectasis are liable to recurrent flare-ups of infection during this progression and sometimes these episodes may be complicated by pneumonia and pleurisy; indeed recurrent episodes of lower respiratory tract infection often raise the possibility of bronchiectasis. The sputum of patients with less severe disease may become mucoid or may dry up altogether during treatment with an antibiotic, whereas in those with severe disease the volume and purulence may only diminish. Bronchiectasis predominantly affecting the upper lobes of the lungs tends to be 'drier', and such may be the case when the structural damage is a consequence of postprimary tuberculosis, ABPA (see Fig. 28.3) or sarcoidosis. Children may produce sputum less frequently than adults, one series recording absent sputum in 32% of a cohort of 96 children despite positive bronchographic confirmation of bronchiectasis [191]. Frequently, cough and sputum production are triggered by postural change, such as lying down at night, rising in the morning or stooping down for some task.

Haemoptysis is also classically associated with bronchiectasis and sometimes it is this more alarming symptom that brings the patient to the physician rather than a chronic or recurrent cough, which may have become accepted as an almost 'normal' state of affairs. The reported incidence of haemoptysis has varied widely, from 4% of 116 paediatric patients [192] to 32% of a surgical series comprising 240 patients of whom the majority were in their twenties [193]. In this series, 12 patients (5%) were described as having 'massive' haemoptyses, four of these patients (1.6%) requiring blood transfusion. The bleeding may come from precapillary anastomoses between hypertrophied branches of bronchial arteries that contain blood at systemic pressure. Such haemoptyses usually occur spontaneously or as a result of superadded infection and has also been described as a complication of iatrogenic thrombolysis or anticoagulation [194,195]. Otherwise unsuspected bronchiectasis may be found on HRCT in 15–17% of patients presenting with haemoptysis [196,197].

Dyspnoea is regarded as a late symptom, other than when it occurs with pneumonia, pleurisy or ABPA with

asthma, and usually indicates widespread lung disease with extensive destruction and fibrosis.

Wheeze is by no means a universal symptom in adults despite the frequent presence of measurable airflow limitation; indeed patients who have demonstrable reversibility of airflow limitation do not always admit to wheeze on direct questioning [39]. Those whose bronchiectasis has resulted from ABPA are often wheezy as they commonly have asthma.

Other coexisting symptoms include general tiredness and malaise and those of upper respiratory infection, particularly sinusitis; at least two-thirds of a series of 116 children had the presence of mucopus in their antral cavities confirmed by aspiration [192]. These symptoms tend to persist into adulthood and it is not uncommon for bronchiectatic patients to have been seen previously in ear, nose and throat clinics; in Streete and Salzer's series [193], 11% of patients had been separately treated for sinusitis.

The presence of symptoms from childhood raises the possibilities of asthma and subsequent ABPA, CF, primary ciliary dyskinesia and congenital immunological defects. CF, primary ciliary dyskinesia and the acquired condition known as Young's syndrome (see above) are all associated with male infertility.

### Signs

Mild cases of bronchiectasis often have no abnormal physical signs. When the disease is sufficiently developed, the characteristic finding is that of persistent early and mid-inspiratory crackles (still often referred to as râles in the USA or crepitations in the UK), which are localized to one or more areas so that they are heard at the same site or sites on repeated examination. These crackles are frequently described as 'coarse' (as opposed to 'fine') and are not shifted by coughing, unlike other low-pitched interrupted noises produced by loose secretions in large airways (see Chapter 6). Although helpful when present, the absence of crackles does not exclude bronchiectasis since in a group of patients with chronic sputum production, auscultatory findings were found to be unreliable in distinguishing between those who had and those who did not have bronchiectasis on HRCT [198].

Clubbing of the fingers and/or toes is a feature of gross disease with prolonged bronchial infection [188]. The frequency with which it occurred in Field's original series of 1949 [199] was 44%, falling to only 7% in her follow-up data published 20 years later [5]. This change is likely, at least in part, to reflect the control of infection by antibiotic treatment, although the deaths of some severe cases cannot be discounted. Nowadays finger clubbing in bronchiectasis, other than that associated with CF, is uncommon in more developed countries.

Signs of collapse and fibrosis may be present in

advanced cases. There may also be cyanosis, with signs of pulmonary hypertension and right heart failure in such patients.

## Functional impairment

The functional impairment in bronchiectasis is related to the extent of lung damage as determined by the number of bronchopulmonary segments involved [184,200]. Other diseases that are much more prevalent in the community may coexist with bronchiectasis partly on the basis of chance, and abnormalities of lung function testing may therefore reflect more than one pathology [200,201].

Measurements of ventilatory capacity and static lung volumes in series of patients with bronchographically proven bronchiectasis tend to show that airways obstruction is the predominant ventilatory defect. Such impairment is often mild and not invariably present, 37% of a series of 116 patients from Edinburgh having an initial forced expiratory volume in 1 s ( $FEV_1$ ) greater than 70% of the predicted value [76]. Another smaller series has shown that 71% of 34 patients with bronchiectasis had airflow limitation in terms of an  $FEV_1$ /forced vital capacity (FVC) ratio of less than 65% [123]. Patients in this series who had 'purulent' sputum had significantly higher residual volume (RV)/total lung capacity (TLC) ratios than those whose sputum was 'mucopurulent' or 'muroid' [123]. The same difference was found between those whose sputum contained elastase and those whose sputum did not [123]. The implication of the findings in these patients was that the presence of infection/inflammation was associated with increased airways obstruction. A series of 23 patients with bronchiectasis from Dublin showed only a mild degree of airways obstruction in terms of  $FEV_1$  and peak flow rates, both of which were 67% of predicted [66]. Another series found evidence of obstruction in terms of reduced  $FEV_1$ /FVC ratios and increased RV/TLC ratios in over half of a group of 42 patients [200]. The degree of airflow limitation (as evidenced by  $FEV_1$ ) has been shown to correlate positively with both the duration of symptoms and the extent of disease on CT examination [202]. Such airflow limitation is likely to be a consequence of both sputum retention and the destruction of smaller side-branching bronchi (Reid's 'bronchitis obliterans'; see p. 805) as part of the bronchiectatic process.

Studies of lung mechanics have also been carried out, showing an elevated pulmonary resistance in a similar proportion and reduced dynamic lung compliance in 41% of 32 cases in whom these measurements were made [200]. No differences in lung function were noted between patients whose bronchiectasis was 'saccular' rather than 'cylindrical' but in whom the distribution of disease was similar [200].

Reversibility of airflow limitation may be present in bronchiectasis. The nature of the pathological changes

might at first suggest that treatment with bronchodilators would produce no benefit; however, the results from a number of studies indicate that their effect should certainly be tried, as a proportion of patients show objective improvement in lung function. Thus 39% of a series of 23 patients showed significant reversibility following a standard dose of fenoterol via a metered dose inhaler [39], and in another small series a mean increase in  $FEV_1$  of 16% was obtained after 5mg of nebulized salbutamol [203]. Improvements in the degree of airflow limitation have also been recorded following treatment with antibiotics [204], although these may be small and clinically insignificant [201]. Patients with bronchiectasis commonly show evidence of bronchial hyperreactivity when tested with substances such as methacholine [205].

In studies of gas exchange, the single-breath diffusing capacity for carbon monoxide ( $DLCO$ ) was found to be reduced to less than 70% of the predicted value in 38% of one series [200]. Pande and colleagues [184], using the steady-state technique, found subnormal values in 87% of their series from New Delhi and observed a correlation between the figures obtained and the number of pulmonary segments involved by bronchiectasis. Further studies of gas exchange were carried out in seven patients who had arterial hypoxaemia of varying severity. All had widened alveolar-arterial  $PO_2$  gradients and a mean true right-to-left shunt of 13.6%. Further evidence of shunting through bronchopulmonary anastomoses has been provided by the findings of (i) higher  $Sao_2$  in blood from the pulmonary artery draining the affected segments, (ii) higher pulmonary arterial wedge pressure in the affected segment and (iii) increased left ventricular output compared with right ventricular output [206]. Bronchospirometric studies of a severely affected lung have shown that although it received one-third of total 'ventilation', it contributed less than 10% of total oxygen uptake [207].

Plainly, radioisotope measurements of regional ventilation and perfusion will be abnormal in bronchiectasis [208]. Unfortunately the limited spatial resolution inherent in these techniques diminishes their value in the pre-operative assessment of bronchiectasis, other than in extensive unilateral disease in which pneumonectomy is envisaged. Radioisotopically labelled particle studies have been used for research purposes to demonstrate abnormalities of mucociliary clearance present in bronchiectasis of any type [209,210].

Lung function in CF is discussed in Chapter 30; suffice it to say that  $FEV_1$  is the best single predictor of mortality [37] and that an increase in RV/TLC ratio and a fall in  $DLCO$  have also been found to correlate with increasing severity of disease in adult patients with CF [211].

In conclusion, lung function tests are of little diagnostic value in bronchiectasis but are useful in measuring the extent of impairment and in demonstrating occasional response to bronchodilators or other treatments. The

simple and highly reproducible tests, such as FEV<sub>1</sub> and FVC, are also the most clinically useful and reliable.

## Other investigations

When a diagnosis of bronchiectasis is suspected on clinical grounds, consideration should be given to predisposing causes that if identified might modify clinical management. These include the possibility of foreign body aspiration, proximal bronchial stenosis as in the middle lobe syndrome or as a result of a slow-growing tumour, ABPA [212] (see Chapter 21), hypogammaglobulinaemia or other primary or acquired immune deficiency syndromes (see Chapter 4), and CF (see Chapter 30) which may occasionally present in adult life [213]. The rare syndrome of primary ciliary dyskinesia may be suspected clinically, although morphological confirmation requires electron microscopic examination of nasal mucosal biopsy material, a facility that is only available in certain centres. Radiographic or CT evidence of paranasal sinusitis may be present but this is often part of a generalized respiratory tract infection rather than the cause of bronchiectasis.

## Microbiology

As is well known, the passage of sputum from the lower respiratory tract to the specimen container results in its contamination by oropharyngeal commensal flora, which may include all the organisms commonly regarded as pathogenic in bronchiectasis. Despite this limitation, the frequent isolation of a relatively small number of different pathogens from purulent sputum, and the clinical response rates based on the sensitivities of these organisms, has led to the general conclusion that they play a clinically important role in bronchiectasis. *H. influenzae* (unencapsulated non-typable strains, not type b) is the bacterium most commonly isolated in such cases of chronic bronchial sepsis, *Strep. pneumoniae* being the second most common in Western series [192,201,214–216]. These are the same organisms as those that predominate in chronic bronchitis. Gram-negative organism such as *Ps. aeruginosa* and less commonly *Klebsiella* spp. may colonize bronchiectatic lung, particularly in patients in whom antibiotics have suppressed the more common invaders or colonizers. These organisms were more common than *Strep. pneumoniae* in one small series from Hong Kong in which lower respiratory tract specimens were obtained by protected bronchial brushing [217]. Patients with bronchiectasis whose lungs are colonized by *Ps. aeruginosa* have been shown to have more extensive and severe bronchiectasis on HRCT than those who do not harbour this organism [218]. *Staph. aureus* may also become a colonist and its presence should always be suspected if a serious clinical deterioration has occurred. Serum precipitins have been regarded as a measure of the patho-

genicity of the more common isolates [219], although not used in routine clinical practice; they have been reported in cases of chronic bronchial sepsis (excluding CF) with frequencies of 83% for *H. influenzae*, 35% for *Strep. pneumoniae*, 29% for *Staph. aureus* and 15% for *Ps. aeruginosa* [214]. The most appropriate culture techniques for isolating common pathogens have been described by Roberts [214]. The relationship between all these organisms and their bronchiectatic hosts is usually one of colonization, contrasting with the situation in pneumonia in which the organism behaves in an acute and invasive manner.

Once present in bronchiectatic lungs both *H. influenzae* and *Strep. pneumoniae* may produce factors that inhibit respiratory ciliary activity [134]. *Ps. aeruginosa* produces various substances, including 1-hydroxyphenazine, with similar effects [119] and also produces another pigment, pyocyanin, from which its earlier name was derived; some evidence exists to suggest that this is toxic to ciliated epithelium [118,220], a property also shared by *H. influenzae* [134]. Both *H. influenzae* and *Strep. pneumoniae* are highly chemotactic, i.e. they stimulate the migration of neutrophil leucocytes from capillaries through the bronchial wall to its lumen. Once present, these neutrophils are likely to result in the release of proteinases, with consequent local pulmonary damage.

Other organisms whose significance is not always clear may also be cultured from patients with bronchiectasis. *Moraxella* (formerly *Branhamella*) *catarrhalis* is one example [221] (see Chapter 13) and it is interesting to note that in Lindskog and Hubbell's series of 215 patients, published in 1955, this organism was the most common isolate [185]. Anaerobic organisms may also play a role. These organisms are probably responsible for the distressing symptom of foul-smelling purulent sputum production that was common in the era before antibiotics. Any effort to grow anaerobes from sputum is wasted because of their invariable habit of massive colonization of the mouth, although transtracheal aspiration has shown that they, along with other unsuspected organisms, occasionally reside in the lower respiratory tract in bronchiectasis [222]. They may be important not only as pathogens in their own right but also as  $\beta$ -lactamase producers, contributing to the failure of  $\beta$ -lactam antibiotics to control other more common pathogens. Other organisms that need not be truly pathogenic may also colonize bronchiectatic lung and also produce  $\beta$ -lactamase, which may protect otherwise susceptible pathogens from penicillins or other  $\beta$ -lactams [223].

Sometimes pathogens may not be isolated from sputum even though it appears to be mucopurulent. This may occur if the patient has recently taken an antibiotic. No pathogens were isolated from the sputum in 39% of one series of 33 bronchiectatic patients, although such patients may nevertheless respond clinically to antibiotic treatment [224]. Unusually, mucopurulence may be caused by

the presence of eosinophils as the main cellular constituent of sputum, as may sometimes occur in eosinophilic pulmonary syndromes.

The pathogenic bacteria in bronchiectasis associated with CF differ from those found in other forms of bronchiectasis in the relative frequency with which different organisms are isolated. Thus infections with *H. influenzae*, *Staph. aureus* and *Ps. aeruginosa* are all common, whereas *Strep. pneumoniae* is a relatively rare pathogen. For a full description of CF the reader is referred to Chapter 30.

Needless to say, whenever there is the remotest possibility of tuberculous infection, the sputum should be stained and cultured for acid-fast bacilli [225].

The role of viruses as a cause of exacerbations of infection in patients with bronchiectasis is uncertain, although it is entirely possible that these organisms may have an important effect by causing further impairment of the already compromised lung defences, thereby allowing greater bacterial proliferation [226]. In a study of US Navy personnel, higher rates of raised adenovirus antibody titres were recorded in 137 patients with bronchiectasis compared with patients with bronchopneumonia, bronchitis and other conditions [227]. The causal association between measles and adenovirus infections has been mentioned above in connection with the pathogenesis of bronchiectasis, as has the causal role of bacteria such as *Bordetella pertussis*.

## Radiological features

### Plain chest radiography

The plain chest radiograph is an unreliable means of diagnosing bronchiectasis as it has been found to have a sensitivity of <50% when bronchography was still widely regarded as the diagnostic 'gold standard' [228]; nevertheless certain plain radiographic features may be taken in support of a clinical diagnosis or may lead to further investigation using HRCT, which has displaced bronchography as the confirmatory investigation of choice. Plain chest radiographic features have been described by Simon and others [229,230] and may include any of the following.

#### *Evidence of dilated bronchi*

**Ring shadows.** Ring shadows produced by dilated bronchi seen 'end-on' (Fig. 28.5). These may be small, numerous and widespread, being one of the causes of the radiographic appearance sometimes referred to as honeycomb lung. Honeycomb lung is not a specific radiographic feature of bronchiectasis and may be seen in other diffuse lung diseases, such as advanced fibrosing alveolitis of any type. Larger (0.5–2 cm diameter) ring shadows may also

occur in bronchiectasis and sometimes contain fluid levels, formed by retained mucopus. They may be localized or widespread, giving the radiographic appearance of cystic lung.

**Parallel lines.** Parallel lines are produced by dilated bronchi viewed 'side-on'. Fine parallel, air-containing, hair-line opacities may be seen in normal subjects close to the hilum and represent a longitudinal view of lobar or segmental bronchi. In bronchiectasis such opacities may be more obvious, their walls being thickened rather than hair-line, and may be more numerous or crowded together, indicating lobar shrinkage (Fig. 28.6). They are sometimes called 'tramlines' because they stand out in parallel fashion against the central lucent column of air that they contain.

**Solid tubular opacities.** If such bronchi contain mucopus they may be seen as solid tubular rather than tramline opacities, looking like a scaled-down column of toothpaste. Their width is obviously variable, depending upon the size of the dilated bronchus, but diameters of 5–8 mm and lengths of 2–4 cm may be attained [229]. They may branch, and when seen *en face* or tangentially may produce 'gloved finger shadows' (Fig. 28.7), each finger of the glove tending to have a rounded end, representing a large dilated bronchus containing mucopus.

#### *Appearances consistent with volume loss*

Appearances consistent with volume loss in one or more lobes or segments may be indirect evidence of bronchiectasis and may be caused by long-standing shrinkage of part of the lung as a result of previous atelectasis and/or fibrosis. Occasionally these changes may be localized enough to suggest a proximal bronchial obstruction, such as may occur in the middle lobe syndrome (see above), in which case HRCT and bronchoscopy help to elucidate. Sometimes the distribution and appearances may raise the possibility of previous tuberculous infection, either in the case of such middle lobe involvement or more usually as a result of upper lobe fibrosis and volume loss. Similar upper lobe changes may result from sarcoidosis and ABPA. 'Fleeting' pulmonary infiltrates on the chest radiograph may have been previously noted in patients with ABPA.

#### *Appearances of pulmonary hypertension*

In extensive disease, there may be evidence of pulmonary hypertension, with prominent proximal pulmonary artery trunks and possible cardiac enlargement.

#### *Kartagener's syndrome*

About half of all cases of the immotile cilia syndrome

**Fig. 28.5** Ring shadows grouped around the hila bilaterally. Two of the larger ones contain small collections of fluid.

**Fig. 28.6** Ring and tramline shadows in the right lower zone of patient with bronchiectasis.

**Fig. 28.7** Gloved finger shadows in right lower zone.

(syndromes of primary ciliary dyskinesia) may exhibit the full Kartagener's syndrome (pp. 795–6), with situs inversus and therefore dextrocardia on the chest radiograph.

#### *Cystic fibrosis*

Systems of scoring the severity of chest radiographic changes in CF (Figs 28.2, 28.8) have been reported, although CT provides more specific information [231,232] (Fig. 28.11).

#### ***Usefulness of plain films in the diagnosis of bronchiectasis***

It has long been appreciated that plain chest radiographs may be normal in patients with bronchiectasis in whom the area of involvement is limited [233]. This is particularly relevant nowadays due to the changing severity of the disorder, so that in one large series plain films in 7% of 112 such patients were reportedly normal [234]. Even when the film is judged to be abnormal, the interpretation of the significance of opacities is highly subjective. A study in which two experienced pulmonary radiologists interpreted plain chest films independently and in ignorance of the bronchographic findings demonstrated agreement on plain radiographic evidence of bronchiectasis in only 9 of 19 patients in whom bronchograms subsequently confirmed the diagnosis. This gave the plain chest radiograph a sensitivity of only 47%, a figure that was not improved

by the additional assessment of a lateral as well as a posteroanterior view [228]. Needless to say, plain radiographs are very inaccurate in localizing the site of bronchiectasis and false-positive results may also be obtained [228].

#### **Bronchography**

Bronchography was for many years the investigation of choice when it became necessary to confirm a diagnosis of bronchiectasis with certainty and was considered mandatory if surgical treatment was contemplated. When the diagnosis seemed highly probable on the basis of the history, physical signs and plain radiographic appearances, bronchography was sometimes omitted when the responsible physician judged that no harm would come to the patient through lack of an accurate topographical demonstration of bronchial pathology. However, it is known that mucopurulent sputum may be produced chronically in patients in whom bronchographic appearances are inconsistent with bronchiectasis [228] and, conversely, that areas of relatively 'dry' bronchiectasis may be discovered bronchographically in patients without such chronic sputum production but who may come to medical attention because of another symptom such as unexplained haemoptysis [235]. Thus in either situation bronchography could fulfil a useful function, if only to put the medical management of the patient on a firmer and more confident footing.

The technique of bronchography involves the instilla-

**Fig. 28.8** Typical diffuse chest radiographic changes of bronchiectasis in a 23-year-old man with cystic fibrosis. Note totally implanted drug delivery system for repeated administration of antipseudomonal antibiotics.

tion of a liquid contrast medium into the tracheobronchial tree. It may be carried out either under general anaesthesia or more usually using a local anaesthetic, in which case the contrast medium may be conveniently directed through a fine catheter (e.g. 4.8 French gauge) introduced through the operating channel of the fiberoptic bronchoscope, which also allows secretions to be aspirated first and enables better penetration of contrast to specific areas of interest [236,237]. Aqueous or oily propylidone (Dionosil) was commonly used for this purpose but has been removed from the market for commercial reasons following the increasing use of HRCT. Propylidone, a highly viscous liquid, was not injected directly through the bronchoscope channel as damage to the instrument might have resulted; furthermore, once the injection had been made vision was 'whited out' and lost. Iotrolan has been used as an alternative contrast medium, with an iodine concentration of 300 mg/mL [238]. This is a clear solution that does not obscure vision. It has a much lower viscosity than propylidone and is therefore easier to inject but requires a faster radiographic recording system and is not without adverse effects, as it may cause headache, nausea and flushing.

Nowadays bronchography is regarded as obsolete in

most centres, HRCT having been found to be a more satisfactory alternative that is diagnostically accurate. Bronchography is an unpleasant procedure for the patient, carrying some morbidity. Allergic reactions to the contrast medium, although unusual, may occur and in inexperienced hands serious local inflammatory reactions have occurred when faulty technique has resulted in soft tissue injection of propylidone when the cricothyroid route was used; in addition, the contrast behaves as a foreign body and gas exchange may be impaired [239]. Despite this, bronchography provided useful information for many years and mention of the typical findings is made below.

### *Bronchographic findings*

Affected parts of the lungs showed areas of bronchial dilatation (Fig. 28.9), described as cylindrical, fusiform, sacular (syn. cystic) or varicose. Such descriptive terms need not imply any particular cause; indeed all have been found in the same patient. Bronchiectatic changes are found more commonly in the left lung and are bilateral in about one-third of cases. Other features include the failure of bronchi to taper as they become more peripheral and a diminished number of bronchial side branches. This last

**Fig. 28.9** Bronchogram showing fusiform and cystic bronchiectatic change in left lower lobe and lingula, with severe bronchitic changes also in proximal airways.

feature is most noticeable beyond the fifth order of bronchi, as these have incomplete cartilagenous support [229], and gave rise to the term 'bronchitis obliterans', which has been used as a synonym for bronchiectasis by some pathologists in the past [180]. Luminal filling defects due to bronchial secretions may be present. Affected areas may show bronchial crowding as a result of pulmonary fibrosis or atelectasis. Proximal fusiform or cylindrical bronchial dilatation, with the preservation of relatively normal distal bronchial branches, is a feature of the bronchiectasis that may complicate ABPA [160].

There have sometimes been difficulties with bronchography in deciding whether changes represent minor degrees of bronchiectasis, particularly as bronchographic abnormalities are described in chronic bronchitis [229]. Such changes may include minor irregularities in the calibre of medium-sized bronchi in particular. The bronchial mucosa may have a beaded appearance and small diverticula (or mucous pits) may arise from the bronchial walls. These have been shown to represent dilated mucous gland ducts [240]. Poor peripheral filling due to bronchial secretions may occur in both chronic bronchitis and bronchiectasis. Whether such changes in a patient with chronic cough productive of mucopus are regarded as being consistent with a minor degree of bronchiectasis or 'purulent bronchitis' is somewhat semantic. It has been well known for many years that temporary bronchial dilatation similar to that seen in bronchiectasis may occur in an area of lung affected by

pneumonia despite clinical resolution and that such reversible bronchiectasis, or pseudobronchiectasis, may persist for several months [241].

The interpretation of bronchograms tends to be subjective, with interobserver variation even between experienced radiologists, so that one study showed disagreement about the presence or absence of bronchiectasis in 7% of a sample of 27 patients whose symptoms were consistent with this diagnosis [228]. When one or other of the two radiologists felt that bronchiectasis was present, the level of disagreement increased from 9% on a single lung basis to 22% for lobar involvement. There were major disagreements about the presence or absence of specific features of bronchiectasis but more concurrent views in terms of overall subjective impression [228].

### Computed tomography

HRCT has become the investigation of choice in bronchiectasis since the last edition of this book was published (Figs 28.3, 28.10, 28.11). As CT has the attraction of being non-invasive and safe, several early studies were carried out to determine whether it might be possible to use this technique as a reliable alternative to bronchography in the diagnosis of bronchiectasis. These showed that *conventional* CT was less sensitive for diagnosing bronchiectasis than bronchography, the sensitivities for 10-mm slices at 20-mm intervals being in the order of 65% [242–244]. When compared with bronchography as the

**Fig. 28.10** Increased retrocardiac lung markings were suspected in the left lower lobe on the chest radiograph (a) of this 53-year-old man with a chronic productive cough. High resolution CT (b) confirmed the presence of an area of bronchiectasis in the corresponding retrocardiac area with great clarity.

'gold standard', Cooke and colleagues [244] found that conventional CT diagnosed bronchiectasis correctly in 71% of 45 bronchiectatic lobes (i.e. sensitivity 71%), indicating that this form of CT cannot be used to rule out bronchiectasis reliably. False-positive results at lobar level occurred in 14% of 81 lobes judged to be bronchographically free of bronchiectasis (i.e. specificity 86%). The development of thin-section HRCT changed this so that sensitivities increased to 82–97% in expert hands [233]. The recommended HRCT technique comprises scanning from apex to base with 1–2 mm cuts at 10-mm intervals, reducing to 5-mm intervals for areas of particular interest. Movement artefact at the bases may simulate bronchiectasis [245] and can be reduced by using a scan time of 1 s or

less and by using the prone position; images are reconstructed using a high-resolution algorithm [233].

HRCT criteria for diagnosing bronchiectasis have been reviewed elsewhere, the two main features being bronchial dilatation and bronchial wall thickening [233]. A bronchus is taken to be dilated if its internal diameter is greater than that of the pulmonary artery branch that accompanies it, measurements being conventionally made in the short axis of both the bronchus and the vessel. Such changes may produce a 'signet ring' appearance. However, minor degrees of apparent dilatation should be treated with caution as a few such bronchi may be found in normal subjects. A lack of normal bronchial tapering towards the lung periphery should be sought in such subjects. Bronchial wall thickening can be said to be present if the thickness of the wall is at least equal to the diameter of the adjacent pulmonary artery branch [246], although a generally accepted definition of this feature has yet to be found. The occurrence of bronchial wall thickening prior to the development of bronchial dilatation has been described in patients with hypogammaglobulinaemia [247]. Air trapping on expiration has been demonstrated as areas of increased transradiancy in patients with severe bronchiectasis, this having been found to correlate negatively with the  $FEV_1$  [248]. It has also been proposed that scanning during both inspiration and expiration may be used to distinguish between an area of cystic bronchiectasis and emphysematous blebs or bullae, the bronchiectatic cysts changing in size with the phase of respiration whereas the bullae do not [249]. Reactive mediastinal lymph node enlargement greater than 1 cm in diameter is not uncommon in bronchiectasis [250]. It is claimed that good HRCT technique can demonstrate the different morphological types of bronchiectasis: cystic bronchiectasis typically shows grouped ring shadows, representing clusters of dilated bronchi that may contain mucopus, sometimes with air–fluid levels; cylindrical bronchiectasis shows dilatation that remains relatively uniform as the bronchus extends peripherally; and varicose bronchiectasis, in which the affected bronchus assumes a beaded appearance. HRCT may sometimes indicate the likely cause of bronchiectasis in terms of morphology and distribution but its discriminatory value has been found to be lacking in individual patients [251]. HRCT has been found to have greater sensitivity than spiral CT when applied to patients in whom bronchiectasis is suspected [252].

## Treatment

The treatment of bronchiectasis may be medical or surgical. Medical treatment aims to relieve and control the symptoms, whereas surgical treatment is intended to eliminate the disease itself. A cure would obviously be preferable if a satisfactory result could be ensured and were it not to carry the inconvenience, morbidity and

small risks of mortality inherent in any major surgical procedure. Such surgical operations were devised before the advent of antibiotics, at a time when bronchiectasis was often socially distressing, physically debilitating and also frequently shortened life [253], so that the choice between a chance of cure and continuing misery was reasonably straightforward. Nowadays the situation differs, since medical treatment with antibiotics has much to offer and surgery therefore plays only a small role.

### Medical treatment

The main arms of medical treatment are (i) the control of lower respiratory tract infection/inflammation with appropriate antibiotic treatment and (ii) the removal of bronchial secretions by postural drainage. Bronchodilators may be useful when there is an obstructive impairment of ventilatory capacity.

### Antimicrobial chemotherapy

Three questions beset the clinician with regard to the use of antibiotics in patients with bronchiectasis: when should they be used, which drug should be chosen and how should they be given?

#### Decision to treat

The decision to treat is usually based on the patient's symptoms. Those whose symptoms are minimal and whose sputum is mucoid require no antimicrobial treatment. Such mild cases are likely to seek medical advice when their sputum becomes mucopurulent, often after an upper respiratory tract infection, and can be treated with a broad-spectrum antibiotic in standard dosage for 1 week or until their sputum becomes mucoid once again, in much the same way as a patient with chronic bronchitis is treated for an exacerbation (see Chapter 23). Antibiotics may render such mild cases infection-free until the next exacerbation follows a viral upper respiratory tract infection. The role of antibiotics in moderate or severe cases whose sputum is chronically mucopurulent or purulent is uncertain. It is the professional inclination of most clinicians when confronted with green or yellow sputum to take steps to clear it. The indirect evidence, cited above, that production of such sputum indicates an inflammatory process that may be causing progressive lung damage via the production of proteases and ciliary dyskinetic factors would support this action [123,126,254,255]. It is perfectly reasonable to attempt to use an antibiotic in such a situation in order to render the sputum mucoid, and indeed some work suggests that patients show improvement both subjectively and in terms of lung function when their sputum clears in this way [204,224,246]. Unfortunately, as discussed below, conventional doses of antibi-

otics either fail to render the sputum mucoid or, if they do, achieve this for only a relatively short time, depending upon the severity of the case [125,224]. The foregoing remarks apply to patients who are in a relatively 'stable' state and there is no doubt that antibiotics should be used vigorously in patients who show evidence of clinical deterioration in terms of increased sputum production or purulence, or following the onset of systemic symptoms.

### Choice of antibiotic

The choice of antibiotic is based on a knowledge of the likely pathogens present in the lower respiratory tract (see pp. 809–810) and their usual susceptibilities. Unfortunately, routine methods of sputum culture do not always provide helpful information and close liaison between the attending clinician and the microbiologist is advisable and indeed essential in difficult cases. Pending any such discussion, antimicrobial therapy is frequently prescribed on an empirical basis. The choice of antibiotic in an exacerbation of infection in a mild case of bronchiectasis, whose sputum is usually mucoid or only faintly mucopurulent, is made by applying the same principles to those discussed under the treatment of exacerbations of chronic bronchitis since the pathogens are frequently the same, notably *H. influenzae* and *Strep. pneumoniae* (see Chapter 23). For a patient who is considered to be a moderate or severe case, with larger volumes of more heavily mucopurulent sputum, then the ability of the antibiotic to penetrate sputum becomes more important [256]. Most acute respiratory infections such as pneumonia (see Chapter 13) and exacerbations of chronic bronchitis respond well to antibiotic treatment, whereas chronic suppurative lung diseases such as moderate or severe bronchiectasis (including CF) and chronic purulent bronchitis unfortunately fail to respond as well. The reasons for this poor response are not entirely clear but are likely to include the following.

- 1 Poor penetration of antimicrobial agents through the thickened, relatively avascular bronchial walls into the lumen, where organisms reside in thick secretions both free and within phagocytes. Such problems of penetration are less likely to arise in acute infections such as pneumonia, in which tissues are hyperaemic so that lung and blood levels of antibiotic are probably better matched [257].

- 2 The infecting organisms may be only moderately sensitive or even resistant to the antibiotics used. In the case of  $\beta$ -lactam antibiotics, such resistance may result from the production of  $\beta$ -lactamases, either by the principal pathogen itself or by other colonists such as anaerobic bacteria. Frank anaerobic infection, characterized by foul-smelling sputum, is now rare in the West but the presence of a smaller lower respiratory tract anaerobic microbial load could be relevant in cases that seemingly fail to respond to antimicrobial treatment.

In view of the foregoing points, when using an antibiotic in a patient whose bronchiectasis is severe enough to produce chronic mucopurulent or purulent sputum, it is necessary to consider both the penetrance of the chosen antibiotic and the most likely pathogens. As *H. influenzae* is the most common pathogen isolated in bronchiectasis and as *Strep. pneumoniae* may also play a role in some exacerbations, the use of amoxicillin (amoxycillin) is a reasonable first choice. This drug has been shown to have better sputum penetrance, dose for dose, than ampicillin, and although the drugs are otherwise very similar this quality makes the former preparation preferable in the treatment of bronchiectasis [134]. Patients who fail to respond clinically to this antibiotic at dosage schedules discussed below may respond to other broad-spectrum antimicrobial agents, when used either empirically to cover the usual pathogens or on microbiological advice. Local patterns of microbial resistance are relevant and the addition of clavulanate (e.g. as co-amoxiclav) may overcome  $\beta$ -lactamase-producing strains of *H. influenzae* and *Moraxella catarrhalis*. One of the newer macrolides (e.g. clarithromycin, azithromycin) may be substituted in the case of penicillin allergy.

There may be prior knowledge of the usual lower respiratory tract isolates in individual bronchiectatic patients dating from previous cultures and this may well influence the clinician in the initial choice of antimicrobial. Thus previous repeated isolates of *Ps. aeruginosa* may lead to the prescription of specific antipseudomonal agents. Similarly, the knowledge that *Staph. aureus* has often been isolated leads to an appropriate response. Sometimes there may be considerable difficulty in achieving sufficient antimicrobial penetration into secretions without causing toxicity at the doses required, in which case patients may require hospital admission for more intensive treatment than can be adequately managed on an outpatient basis. Allergy to penicillins places similar restrictions on management.

#### **Dose, route and duration**

The optimum dose of antibiotic, duration of treatment and route of administration have not been clearly established. In the case of oral amoxicillin, it has been shown that the minimum bactericidal concentration in the sputum of patients with bronchiectasis is only satisfactorily achieved with doses in the order of 3 g twice daily [134]. Ampicillin at the same dose produces sputum levels only one-fifth as high. However, this does not mean that all patients with bronchiectasis should receive such high dosages.

Another study showed that patients with mild bronchiectasis (mucopurulent sputum only in exacerbations) responded satisfactorily to a 2-week course of amoxicillin at standard oral dosage of 250 mg three times daily [224]. Those whose sputum was usually mucopurulent and occasionally purulent also responded to the same

schedule but the median response time was shorter, being only 9 days before the purulence returned. Very few patients with more severe bronchiectasis (sputum persistently purulent) responded to this standard regimen, although about 60% did respond to 3 g amoxicillin 12-hourly [224]. These improvements may be accompanied by a sense of increased well-being and a reduction in symptoms; furthermore, such improvement may occur despite the presence of pretreatment microbiological isolates suggesting the presence of resistant organisms [224]. Most clinicians reserve such high-dose treatment for patients who have shown some clinical deterioration rather than using it in patients whose sputum is mucopurulent or purulent but who are considered to be in a 'stable' state.

Although it has been shown that high-dose amoxicillin treatment reduces the number of microorganisms infecting the lower respiratory tract while treatment is in progress [63] and that such treatment appears to produce some benefit when administered for short periods, it has not yet been shown whether prolongation of this treatment prevents the progression of bronchiectasis in the long term. The rationale for long-term treatment in bronchiectasis has been that diminution of the inflammatory process in the lungs may prevent further destruction and fibrosis and also that it might reduce the frequency of clinical exacerbations. The published long-term trials of antibiotics in bronchiectasis are somewhat sparse. In 1957, a Medical Research Council trial using 2 g of tetracycline twice weekly for 12 months reported a reduction in days off work, days in bed and episodes of fever in the treatment group [258]. Since the results of this study some clinicians have used tetracycline or other more modern antibiotics prophylactically, either through the winter months when upper respiratory tract infections are more prevalent or throughout the year, according to their judgement of the severity of the case [259]. It has to be said that the evidence of benefit accruing from such standard dose regimens is slender. In a more recent trial, patients with bronchiectasis received high-dose oral treatment (amoxicillin 3 g twice daily) on a placebo-controlled basis for a period of 8 months. There was no significant difference in the frequency of exacerbations but severity was judged to be diminished and less sputum was produced between exacerbations. Patients receiving active treatment also spent less time in bed and off work than those treated with long-term placebo, in similar fashion to the old Medical Research Council trial [260].

Long-term treatment with antibiotics at doses that may achieve suboptimal sputum levels also carries the potential risk of selecting resistant strains of the primary pathogen or of promoting the overgrowth of secondary pathogens, such as *Ps. aeruginosa* or *Klebsiella* spp. [261]. As with all long-term medication, the potential for adverse effects also has to be weighed against the likelihood of

benefit. High-dose amoxicillin given long term seems to be remarkably well tolerated by some but not by others, the principal adverse effects being rashes and diarrhoea [257,262]. It is less expensive than was previously the case if non-proprietary capsules rather than sachets are used but it is still not clear whether the cost is offset by the benefits. Any  $\beta$ -lactamase-producing organisms may sometimes be dealt with by combining 2.75 g amoxicillin with one co-amoxiclav 375-mg tablet. Patients whose exacerbations fail to respond to oral medication or whose condition is considered more serious from the outset are often treated with parenteral antibiotics *ab initio*.

'Pulses' of regular intravenous antibiotics, for example for 2 weeks at 3-month intervals irrespective of symptom state, have been used by some centres in the subgroup of patients with bronchiectasis caused by CF [263], although controlled data on the unequivocal benefit of such an approach are presently lacking. Such regularly repeated intravenous antimicrobial therapy eventually produces difficulties with venous access, in which case a totally implantable drug delivery system may be an advantage [264–266] (see Fig. 28.8).

Antibiotics are sometimes used in nebulized form (Chapter 9, p. 216) to treat lower respiratory tract infection in patients with bronchiectasis [224,267]. This form of treatment is most commonly reserved for *Ps. aeruginosa* and, while sometimes used in conjunction with parenteral antibiotics in acute exacerbations, is likely to be more effective when given in the longer term between exacerbations by reducing the pseudomonal colonial population and thereby also reducing airway inflammation. The polymyxin antibiotic colistin (1–2 megaunits twice daily after postural drainage) is commonly used in this regard in adults with CF [268]. Tobramycin may be used as an alternative [269].

It follows that antibiotics may be used either intermittently to treat symptomatic exacerbations of infection or preventively in more severe cases between exacerbations using long-term oral therapy, intermittent intravenous 'pulsed' therapy or long-term nebulized therapy singly or in combination. The great majority of patients are dealt with by treatment of symptomatic exacerbations with courses of oral antibiotic, the magnitude of the dose and the duration of the course being varied according to the perceived severity of the disease. A significant minority have an inadequate symptomatic response with continued functional deterioration, in which case one or other of the alternative methods may have to be tried.

### Postural drainage

Physiotherapy, including postural drainage of chest secretions, has been regarded for many years as a mainstay in the treatment of bronchiectasis. Fluoroscopic studies in patients with bronchiectasis have demonstrated that

instead of resulting in expectoration of sputum, cough may cause complete collapse of the more proximal part of an affected bronchus, possibly due to the destruction of supporting cartilage, so that more distally situated secretions tend to become trapped in the lung periphery. Indeed fiberoptic bronchoscopists know to their annoyance that coughing causes even healthy segmental bronchi to collapse temporarily. This effect of coughing is of no consequence in ordinary circumstances as the mucociliary escalator wafts secretions up to the more rigid proximal airways that can maintain their patency despite a cough. However, in bronchiectasis the usual sputum clearance mechanisms are disrupted by (i) swamping of the normal blanket of mucus via excessive secretion, (ii) the replacement of ciliated epithelium with squamous cells so that the mucociliary escalator cannot operate for the area subtended by this denuded mucosa and (iii) the elaboration of various factors that produce ciliary dyskinesia, as previously outlined. The sum effect of this is that cough alone is of limited usefulness in patients with bronchiectasis who produce excessive tracheobronchial secretions [270]. This is particularly true when, as is usual, the more dependent parts of the lungs are the areas most affected, since bronchial secretions do not readily drain from these zones and their accumulation produces a 'sump' or 'septic tank', which acts not only as a constant source of damaging inflammatory substances but also as the force behind acute exacerbations of infection.

When sufficient bronchial secretions are produced, this sump requires drainage that is best assisted by the force of gravity using so-called postural drainage, often known to patients as 'tipping'. Postural drainage has been shown in the short term to increase rates of mucociliary clearance [271,272] and to increase the expectoration of sputum, particularly in patients whose secretions are copious. It has also been found to improve airway function in the short term, although such experience is not universal [273,274].

The technique of postural drainage is designed to assist the removal of bronchial secretions from the more peripherally affected parts of lung towards the more rigid bronchi near the hilum, which once reached can be emptied by coughing. A knowledge of the affected lobes is necessary to achieve optimal drainage. The disposition of affected sites may be suggested by physical examination or by plain radiographs but is only accurately demonstrated by bronchography or nowadays almost invariably by HRCT.

The basal bronchi may be emptied in someone of moderate strength and agility by the technique of leaning forwards over the edge of a low bed using the arms as a support against the floor. Older patients may have to manage by using cushions, a folding frame, plastic-covered foam wedge, 'bean bag' or by arranging for the foot of the bed to be elevated. Drainage of the middle lobe or lingular bronchi is achieved if the patient lies supine with the foot of the bed elevated and the affected side

lifted off the bed by pillows. Once correctly positioned, the patient is instructed to take deep breaths in order to aid drainage from the peripheries. After 10–15 min, the patient should cough in order to clear the larger air passages. Sometimes the patient finds that spontaneous coughing occurs once an upright posture is regained and that most of the sputum is cleared in this way.

These procedures should be practised under the supervision of a chest physiotherapist, who should have been told which areas of the lung are thought to be bronchiectatic and require drainage. Chest percussion may be used as an adjunct to tipping. However, the evidence that this so-called 'ketchup bottle method' is effective in bronchiectasis is insubstantial [272,275,276]. It is helpful if the patient's spouse or other relative attends one or two physiotherapy sessions, in the hope that this will reduce embarrassment on the part of the patient and improve compliance, which is often poor despite encouragement [277,278].

If possible, postural drainage should be carried out several times daily during exacerbations that are being treated in hospital. Each session should be continued until the chest is apparently 'dry'. Patients who produce about 30 mL (an eggcupful) of sputum per day or more should be encouraged to tip themselves daily on rising and on retiring as a matter of course. Resistance to this advice is often strong, and in a stable patient postural drainage once daily, increasing to twice daily in an exacerbation and certainly if an antibiotic is being taken, may have to be accepted. It is unlikely that patients with only a little sputum production benefit from postural drainage, which should probably be reserved for those who produce 30 mL daily or more [279,280]. Humidification of inspired air prior to physiotherapy may aid tracheobronchial clearance [281].

It is now usual to combine traditional postural drainage with the forced expiration technique, or 'huffing', in which forced expirations without closure of the glottis are made, thereby avoiding the strongest compressive phase of coughing. This is followed by a period of diaphragmatic breathing in order to avoid the worsening of wheeze that sometimes occurs following a forced expiratory manoeuvre [282,283]. The purpose of this modification is to reduce the bronchial collapse induced by coughing, which might actually tend to trap secretions peripherally. 'Huffing' should therefore propel secretions from the periphery to the more rigid central airways, after which coughing expels them.

The place, if any, of other techniques, such as high-frequency chest wall compression [284] and high-frequency mouth oscillation [285], have yet to be determined. Although no study has been carried out to demonstrate objectively that physiotherapy has an effect on morbidity or the long-term outcome in bronchiectasis, there is usually short-term benefit to the patient [273] and

postural drainage remains central to the treatment of this group of patients.

### Other medical treatment

The potential benefit of bronchodilators has already been referred to and when tests of ventilatory function show evidence of airflow limitation, as is often the case, it is common practice to prescribe an inhaled  $\beta$  sympathomimetic to be taken by metered dose inhaler, especially when there is evidence of a significant improvement of  $FEV_1$  [66,203]. Airways obstruction is predictably irreversible in some patients and indeed a paradoxical effect has been reported in children with CF [286]. Increased sputum yield and increased clearance of secretions, as measured by radioaerosol marker, has been demonstrated in a group of patients with 'stable bronchiectasis' when they received a nebulized bronchodilator before chest physiotherapy [287]. There were also small but significant improvements in lung function indices that were not seen following nebulized saline [287].

A trial of corticosteroids, such as prednisolone 30–40 mg daily for 10 days, may be attempted when there is a failure to obtain an adequate response to bronchodilators in patients with significant airflow limitation, provided that the patient is in a stable phase, so that an objective assessment of response may be made. Isolated reports of benefit are recorded in the literature [288], for example in some cases of bronchiectasis occurring in association with inflammatory bowel disease [141,143], but if objective improvement is not obtained then there is no point persisting with this potentially harmful line of treatment and, generally, long-term adverse effects preclude their use. However, oral corticosteroids are indicated in the treatment of the eosinophilic lung infiltrates associated with ABPA (see Chapter 21) in order to suppress inflammation that may lead to further bronchial damage; indeed long-term suppressive therapy with a maintenance dose of corticosteroid may well be indicated in this condition.

It has been postulated that high-dose inhaled corticosteroids may reduce the inflammatory response in bronchiectasis; 750  $\mu$ g beclometasone (beclomethasone) dipropionate every 12 h was shown to reduce sputum production in a group of 20 patients with bronchiectasis, with diminished coughing and small improvements in indices of ventilatory function [289].

It is not generally accepted that mucolytics have a role in the management of bronchiectasis, other than the case of recombinant human DNase (rhDNase or dornase alfa) in certain categories of patient with CF (see Chapter 30), since much of the viscoelasticity of sputum in this condition has been shown to be due to DNA released from neutrophils and bacteria. Short-term rhDNase has not been shown to be of benefit in adults with bronchiectasis not caused by CF [290]. *N*-Acetylcysteine is a mucolytic that

reduces sputum viscosity by cleaving glycoproteins. Its prolonged administration via the nebulized route causes airway irritation and inflammation and it may also cause bronchoconstriction. Although claimed to be useful in some patients with bronchiectasis, orally available preparations are generally regarded as of unproven benefit. The nebulized form has been supplanted by rhDNAse in CF.

Rare cases of bronchiectasis that occur in association with immunodeficiency syndromes (see Chapter 4) are subject to recurrent lower respiratory tract infection and may be treated with normal human immunoglobulin obtained from the pooled plasma of healthy donors. Such treatment may make a substantial impact on the clinical well-being of such patients with panhypogammaglobulinaemia or selective immunoglobulin deficiencies and impedes the progression of lung damage. It may be given intravenously at a dose of at least 200 mg/kg at 2-weekly intervals or 400 mg/kg at 4-weekly intervals, according to clinical assessment. Mild anaphylactoid reactions may occur initially and can be prevented by giving intravenous hydrocortisone before the first three infusions and running them at a slower rate of 1 mg/min.

Gastro-oesophageal reflux sometimes exacerbates lower respiratory tract symptoms and should be treated medically if present.

The long-term outcome of domiciliary nasal intermittent positive pressure ventilation in a small group of patients with hypercapnic ventilatory failure due to end-stage bronchiectasis has been found to be poor [291].

### Surgical treatment

Surgical treatment plays only a small role in the present-day management of bronchiectasis in Western countries, having had its greatest popularity in the 1950s and early 1960s at a time when the disease was still highly prevalent and when thoracic surgical procedures had become relatively safe. At the same time, medical treatment was unable to control symptoms adequately in many patients. As the results of antimicrobial treatment improved during this period, the place of surgery began to be questioned [292–295] and the pendulum has since swung well in the direction of management by medical means. Unfortunately, this has led to the widespread belief that surgery has no role in the treatment of bronchiectasis, which is erroneous. Elective surgical treatment should not be considered ordinarily unless:

- 1 the diagnosis has been confirmed radiographically (technically adequate HRCT has replaced bilateral bronchography in virtually all centres);
- 2 the disease is sufficiently localized to one lung or to part of one lung to enable curative resection;
- 3 the residual lung is judged to be sufficiently healthy in terms of measured lung function;

4 the patient is significantly disabled by persistent sputum production, recurrent infective exacerbations or haemoptyses despite all reasonable medical measures having been taken over a period of at least 12 months;

5 there is no persisting systemic causal factor likely to result in the development of new disease in previously unaffected lung.

It is the common experience in countries with developed and evenly spread health services that cases fulfilling these requirements are rare. Thus, on the one hand, most patients with sufficient disability as a result of bronchiectasis have disease that is too widespread to be amenable to surgery and, on the other, those patients with localized disease may have symptoms that are too minor to justify surgery with its attendant risks even though these may be small.

Published surgical results are frequently difficult to evaluate as patterns of referral and operative policies differ from one centre to another and cases have usually been collected over many years, during which period treatment policies inevitably change; furthermore, prospective trials comparing operative and non-operative treatment for patients with disease of similar extent are non-existent.

The largest surgical series is that of Le Roux and colleagues [7], which is based on a South African experience of 2776 bronchographically confirmed cases; 449 (16%) of these were children aged under 10 years, of whom 247 (55%) underwent surgery; 2327 patients were aged over 10 years and of these one-third (756) underwent resection; 85% of those operated on were said to have been 'satisfied with the symptomatic relief' provided by pulmonary resection. The overall resection rate after initial assessment was 36%, being 55% for those aged under 10 years and 33% for those over 10. The operative mortality was 1%. Postoperative empyema occurred in 1.5%. Overall, 64% were considered unsuitable for surgery, the usual reasons being extent of disease or 'poor respiratory reserve'. Another series of 125 patients operated on from 1952 to 1962 was reported to show complete absence of symptoms in 55% of unilateral cases. A further 42% were said to be physically fully active but with occasional cough or clear sputum. Most patients were aged 10–40 years and there was one operative death [296]. In the modern antibiotic era, a more recently reported series of 134 patients aged 4–89 years (mean 48 years) treated surgically for bronchiectasis at the Mayo Clinic achieved complete cure in 59% for an operative mortality rate of 2.2% [297]. The usual indication for surgery in this group was 'failure of medical treatment' but some of them had been free of chronic symptoms and were operated on for haemoptysis, lung abscess or 'unresolved pneumonia'. Unsurprisingly the results were better when complete resection was achieved [297].

From the surgical viewpoint, patients whose symptoms

can be controlled medically but which recur when treatment is stopped are preferred for reasons of lower risk, as they can be well prepared preoperatively [7]. Pneumonectomy has been satisfactorily carried out provided that the remaining lung is normal, although it appears to be a higher-risk procedure when the lung damage is a consequence of remote tuberculous infection [298]. When less than the whole lung is removed, sufficient normal lung should be left to enable its expansion to fill the available hemithoracic space. This may be best achieved when the bronchiectatic lung removed is shrunk, fibrotic and functionless from childhood so that the remaining lung has undergone compensatory growth to fill the hemithorax. The question of bilateral surgical resection in bronchiectasis is controversial. Some series report that the degree of improvement after the first operation on the worst affected lung is often such that further surgery was not proceeded with even though originally envisaged [7,299]. Others have reported complete relief from symptoms in 34% of patients with bilateral resections and that a further 53% were left with minimal symptoms [296]. The optimal age for surgery is undetermined. It has been shown that minor bronchographic changes in very early childhood may progress to undoubted bronchiectasis in one-quarter of cases and that resection should be postponed until patients are aged 6–12 years by which time the full extent of the disease has declared itself [191].

A retrospective study compared 24 patients who underwent surgical treatment with 16 patients of similar age and disease extent who were also considered to have been surgical candidates but who were treated medically because of either non-referral or patient preference; 46% of those treated surgically became asymptomatic compared with 12% of the medically treated group. The authors concluded that medical treatment is unwarranted in disabling disease if the patient is fit for surgery [300]. This view is supported by others who followed 87 children considered to be candidates for surgery but who were treated medically [191]; over 90% of these patients continued to experience symptoms.

From the foregoing it can be seen that surgical treatment in well-selected cases of bronchiectasis produces excellent results and that it offers a chance of cure. Localized bronchiectasis subtended by a bronchial stenosis that produces symptoms such as recurrent cough, fever and pleuritic pain appears to be the type most amenable to successful resection. Few would disagree that distressing localized disease that is uncontrolled by medical means should, in an otherwise fit patient, be submitted for surgical consideration. However, with the decline of whooping cough, measles and tuberculosis in the more developed countries, the opportunities for such curative treatment have become increasingly few and far between.

Young adults with severe bilateral end-stage bronchiectasis may be amenable to double lung or heart–lung trans-

plantation. This is most likely to be an option in carefully selected patients with CF (see Chapters 30 & 59) in whom actuarial survival at 1 year and 3 years after transplant of 78% and 65% has been reported [301,302]. Other patients with bronchiectasis are much less commonly considered for transplantation [303,304].

Occasionally surgical resection has to be carried out for moderate or severe haemoptysis that may be recurrent, arising in an otherwise fit patient with a relatively localized area of bronchiectasis. In such previously undiagnosed cases, bronchoscopy may be helpful by establishing the anatomical site of the bleeding.

## Prognosis

Numerous personal series of patients with bronchiectasis have been published over the years and the outcome of the disease differs confusingly from one set of results to the next (Fig. 28.11). This is unsurprising since patterns of referral to individual centres and local policies regarding selection for a given method of treatment are highly variable. These difficulties are compounded by the facts that (i) bronchiectasis is a morbid anatomical end-result with many different pathogenic factors, (ii) the natural history of the disease may span decades, during which attitudes towards treatment have gradually changed following the availability of effective antimicrobial treatment for suppurative lower respiratory tract disease and (iii) the prevalence of the disease has declined greatly in the West, so that countries that possess the facilities to conduct controlled trials (notable by their absence in the literature) no longer have sufficient numbers of patients on which to carry them out.

Notwithstanding these difficulties, a number of general observations can be made and conclusions drawn from earlier published work.

Fig. 28.11 Diffuse changes of bronchiectasis in a 22-year-old man with cystic fibrosis.

1 Poor prognosis is usually a function of the extent of disease and it is in extensive cases that a relentless deterioration to a fatal outcome, sometimes in association with cor pulmonale, may be seen [5]. The mortality rate in a series of 116 patients comprising both surgical and medical cases was 19% over an average follow-up period of 14 years, with a mean age at death of 53 years [76]. However, extensive disease was not incompatible with long life even well before the advent of antibiotics, Laënnec recording the case of an 82-year-old *maitresse de piano* whom he saw shortly before her death. She had steadily followed her occupation despite the presence of a persistent cough since the age of 16 and at postmortem examination was found to have gross bronchiectasis involving the whole of the right lung and the left upper lobe [1]. However, before the introduction of antibiotics others have cited mortality rates of 30–50% over a 10-year period, the selection of severe cases no doubt contributing to this gloomy outcome [253,305].

2 There was a sharp fall in the incidence of cases of bronchiectasis attending children's hospitals between 1950 and 1960, at the time broad-spectrum antibiotics were introduced [5]. Present-day treatment with antibiotics must have affected the short-term outcome and may well also have affected the long-term prognosis of bronchiectasis [5].

3 In a 20-year follow-up study of patients from childhood, when bronchiectasis was diagnosed, to adulthood (mean age 28 years), Field [5] found that both surgically and medically treated groups tended to improve symptomatically in the second decade, remaining static in the third and fourth. It has been known for over 50 years that spontaneous improvement may occur in some cases of bronchiectasis, a number of whom become 'dry' or symptom-free [3,306–308]. A series of 116 patients with proven bronchiectasis showed that decline in FEV<sub>1</sub> was no greater than expected in 80% of patients, and that in a further 15% it was of the order found in cigarette smokers with mild airways obstruction [76].

4 Whereas symptoms may improve with time in some patients, in others the disease may extend radiographically, evidence of new disease being found in 19% of 79 patients in one bronchographically evaluated series [192]. In a bronchographic series of 195 Alaskan children, Wilson and Decker [191] distinguished between (i) progression of disease from early ill-defined changes to full-blown bronchiectasis, this being common in early childhood and occurring in 26% of their series, and (ii) extension of disease to previously healthy and uninvolved bronchi, which was rare, occurring in only 2% of cases.

5 The results of some surgical series have already been mentioned and, as might be expected, improvement is evaluated in subjective terms so that it varies with individual selection criteria, period of follow-up, etc. Three series

over the last two decades have recorded figures ranging from 50% of patients achieving 'freedom from symptoms', 59% having a 'complete cure' to 75% being 'well or much improved' [191,297,309].

6 Some causal or associated disease may affect the prognosis. Thus the outcome is inevitably much worse in CF (see Chapter 30) and asthma has also been found to have an unfavourable effect on the mortality rate [5]. Bronchiectasis occurring as a result of tuberculosis is paradoxically associated with a better outcome [5], possibly because of the predominantly upper lobe involvement, secretions draining better from these zones.

Life expectancy for *most* patients is good, although there is a tendency towards gradual progression of the extent and severity of disease with increasing symptomatology.

## Complications

### Infective exacerbations

Infective exacerbations occurring in patients with bronchiectasis are marked by both increased volume and purulence of sputum as described above. They may follow upper respiratory tract infections in much the same way as exacerbations of chronic bronchitis. Occasional progression to pneumonia occurs and this may be indicated by patchy infiltrates on the chest radiograph, situated in the region of affected bronchi. Suppurative pneumonia and lung abscess are both uncommon but well-recognized complications, the latter occurring in either an area of pneumonia or unaffected lung, presumably as a result of endobronchial dissemination of infection. Pleuritic pain may be associated with any of the foregoing infections or may occur in apparently isolated fashion as dry pleurisy, sometimes recurring at a given site. Other pleural complications are unusual and include pleural effusion, empyema and pyopneumothorax.

Extensive lung fibrosis may progress to respiratory failure and cor pulmonale, this having been found at post-mortem examination in over one-third of 22 fatal cases of a series of 116 patients [76].

### Haemoptysis

Haemoptysis occurs commonly in bronchiectasis, usually in association with lower respiratory tract infection but occasionally as an isolated event [235] and as the declaring symptom. Such episodes are usually small, although major (>200 mL per 24 h) or rarely massive (>1000 mL per 24 h) haemoptyses may occur [299], this being an indication for prompt admission to either a thoracic surgical unit or to a facility with access to an interventional radiography unit with expertise in bronchial artery embolization techniques. Such patients are at risk of asphyxiation and should be placed in a head-down lateral decubitus posi-

tion with the bleeding lung dependent (if this side is known) in order to protect the other lung. Rigid bronchoscopy should be carried out by a thoracic surgeon as soon as possible if bleeding continues, in order that blood may be removed and to attempt localization and tamponade of the likely bleeding site. Emergency thoracotomy and resective surgery may need to be undertaken when bleeding is brisk and continuous. Centres with appropriate radiological expertise may be able to carry out bronchial arteriography to localize a bleeding point, which may then be embolized [310]. Repeated moderate haemoptyses may also be an indication for elective surgical excision of the source of bleeding, unless a bronchial feeding vessel can be localized and embolized [311]. A retrospective study of major or massive haemoptysis due to various causes, conducted before the development of embolization techniques, found that only 4 of 59 such patients underwent surgery and that no patient with bronchiectasis who was managed conservatively had a fatal outcome [195].

### Sinusitis

Chronic paranasal sinusitis occurs in a high percentage of patients with bronchiectasis and is very common in severe cases. It has never been entirely clear whether the sinusitis occurs as a precursor or as a sequel to bronchiectasis, although the latter is more probable. Lindskog and Hubbell [185] found sinusitis in 12% of 215 patients with bronchiectasis; 27% of those whose symptoms had been present for less than 10 years had sinusitis compared with 45% of those whose symptoms exceeded this period. This finding suggested that sinusitis was a consequence of bronchiectasis rather than a cause; nevertheless once chronic infection is established in the upper respiratory tract, it may act as a feeder so that it tends, like a trickling down-pipe, to perpetuate infection in the septic tank of bronchiectatic pulmonary infection. The management of sinusitis is discussed in Chapter 12. Radical measures to clear sinusitis are probably not worth attempting unless the bronchiectasis has been controlled either medically or surgically. Cases in whom bronchiectasis has been treated by surgical excision and in whom sinusitis persists should

be considered for endoscopic surgical treatment (antrostomy) of their sinus infection if it fails to respond to adequate medical measures. These measures include a dual approach, in which an attempt is made to suppress paranasal mucosal inflammation with an aqueous solution of topical steroid solution, applying it in a head-down and forward position in order to allow better distribution. This is intended to allow secretions to drain through hitherto blocked ostia and may be combined with a prolonged course of an appropriate broad-spectrum antibiotic if the secretions are thought to be infected [312,313].

### Other complications

Brain abscess used to be a feared complication of bronchiectasis in the era before antibiotics, occurring in 12% of 193 fatal cases of bronchiectasis in three old series [188,314,315]. It may complicate limited bronchiectasis but is nowadays rare [316]. The absence of abscess formation elsewhere suggests that infection may reach the brain via the vertebral plexus of veins or possibly from paranasal sinus infection.

Amyloidosis [317,318] is now a very rare complication of bronchiectasis. Fibrils of amyloid A protein may be deposited in any tissue in the body. If this increases sufficiently in quantity, it may disrupt normal cellular structures, producing functional disturbances. It most commonly presents with proteinuria as a result of renal glomerular disruption. Hepatosplenomegaly and cardiac involvement may also occur. The diagnosis can be confirmed by histological examination of tissue, rectal mucosal biopsy often being used for convenience.

Disseminated aspergillosis has been described as a rare complication of bronchiectasis [319].

Systemic hypersensitivity vasculitis has been reported in association with bronchiectasis infected by *Ps. aeruginosa* [320].

There have been occasional cases of lung cancer reportedly developing in an area of scarred bronchiectatic lung [321].

Operative complications include haemorrhage, atelectasis, pneumonia, empyema, bronchopleural fistula and pneumothorax [185,192,193].

# BRONCHIOLAR DISEASE

ANTHONY SEATON

The bronchioles have been regarded aptly as a silent part of the lung, unassociated with well-recognized diseases, invisible on radiography and the function of which is difficult to measure physiologically. Older readers may recall the interest engendered in the 1960s when it was suggested by Hogg and his Montreal colleagues [1] that the bronchioles were the site of the lesion that leads to chronic airflow obstruction in smokers, and the subsequent search for a simple test of small airways function that could be used for screening purposes. Paediatricians also have long been aware of the infective bronchiolitis syndrome in infants, most usually associated with respiratory syncytial virus. More recently, however, it has become apparent that there are a number of relatively unusual but important bronchiolitic syndromes in adults apart from that associated with smoking.

The bronchioles are airways without cartilage, lined by bronchial epithelium and leading into air sacs. They comprise three to four orders of conducting or membranous bronchioles, the terminal ones in turn bifurcating into the first of two to three orders of respiratory bronchioles. These last give rise directly to some alveoli before ending in air sacs. There are approximately 25 000 terminal bronchioles. Therefore it is not unreasonable to suppose that they may be affected not only directly but also indirectly, either by disease arising primarily in alveoli or by extension of disease occurring in the cartilagenous airways. The former situation is recognized for example in extrinsic allergic alveolitis, which were it not so difficult to pronounce might more accurately be called allergic bronchioloalveolitis; the latter situation is found in cigarette-induced lung disease.

Three factors have contributed to an increased recognition of the importance of bronchiolar disease. The first was the work on the physiology of small airways as part of a search for a means of early detection of those who would become disabled by airflow obstruction [2]. The second was the recognition of a wide spectrum of pulmonary syndromes that caused breathlessness but which did not fit easily into traditional classifications of lung disease [3,4],

and the third was the increasing availability of relatively safe and more acceptable methods of lung biopsy.

## Physiological considerations

Because there are so many bronchioles, each with a diameter of about 1 mm, it would clearly require a considerable number to be obstructed before this would have a result comparable to the effect that obstruction of the larger-diameter major conducting airways has on crude overall measurements of airflow obstruction, such as forced expiratory volume in 1 s (FEV<sub>1</sub>). Thus substantial obliteration may occur before symptoms and evidence of airflow limitation become apparent. However, other functional impairment may be detected earlier. For example, air may be trapped distal to partly occluded airways leading to a rise in residual volume and closing volume. Similarly, the presence of some narrowed small airways may produce different time constants in different parts of the lung and this may cause reductions in dynamic compliance when measured at increasing respiratory rates. These tests have provided useful information but have, perhaps undeservedly in the case of closing volume, fallen into disuse. Flow rates measured at low lung volumes may also indicate small airway obstruction, although this test proves too variable in practice to be of diagnostic value. Diffusing capacity for carbon monoxide may also be reduced, either if alveoli are involved in the pathological process or if access of the gas to the alveoli is reduced in the 10 s available during the single-breath test.

It should be apparent from this discussion that there is no one test or even combination of tests that provides diagnostic information in patients with bronchiolar disease. The patterns of abnormality described in the literature are quite variable, and need to be considered with other evidence in coming to a diagnosis.

## Syndromes of bronchiolitis

There is no generally agreed clinical classification of

bronchiolar diseases, and many of the described syndromes are relatively unfamiliar to chest physicians. Review of the literature suggests that the 'splitters' have had a field-day, many syndromes being described on the basis of a search through pathological and clinical archives in order to describe a few cases with apparently similar features under a new name. Sometimes the same condition appears at different dates described by different names. It is important for the clinician to remember that there are in fact relatively few pathological manifestations of bronchiolar disease and that these represent inflammatory reactions to a wide range of possible causes. Clinical classifications have tended to depend on cause, known or unknown, while pathological classifications have relied on distinctive histological features. A relatively simple clinical classification suggested by the author is given in Table 29.1.

The obliterative type of bronchiolitis may be separated pathologically into two subtypes: one in which there are intrabronchiolar plugs of organizing connective tissue (proliferative bronchiolitis obliterans) and one in which the bronchiolar walls are inflamed and fibrosed with marked narrowing or complete obliteration of the lumen (constrictive bronchiolitis). The former is often accompanied by extension of the proliferative changes into alveolar ducts and alveoli, a lesion referred to as bronchiolitis obliterans with organizing pneumonia (BOOP) or, confusingly, cryptogenic organizing pneumonia.

**Non-oblitative bronchiolitis**

**Infective bronchiolitis**

Viral infections may cause direct inflammation of the airway mucosa at any point, sometimes leading to desquamation and increased airway reactivity. In children the most common syndrome is bronchiolitis due to respiratory syncytial virus occurring before the age of 1 year

[5]. Almost all infants are infected by this virus and a proportion develop cough, wheeze, a hyperinflated chest and inspiratory crackles. The predominance of bronchiolitic symptoms in this age group is probably explained by the relatively larger contribution of the not fully developed bronchiolar airways to overall airflow resistance in such infants. Some 2–3% are sufficiently ill to require admission to hospital. While some children continue to suffer recurrent wheezy attacks afterwards, it seems likely that these represent those already predisposed to asthma and that the infection itself does not lead to this disease [6–8].

In adults it is commonplace to see patients with persistent cough after viral infections. These patients often have increased airway reactivity and respond poorly to bronchodilators and corticosteroids. It may be suspected that bronchiolitis is present in some, but histological evidence is not available. The usual course is towards slow recovery.

**Toxic bronchiolitis**

Persistent cough without airflow obstruction is a frequent sequel to inhalation of a very wide range of irritant gases or fumes. In more severe cases airflow obstruction is present and this is often sufficiently variable for the diagnosis of asthma to be made. In these cases airway hyper-reactivity is present and the syndrome is usually called reactive airways dysfunction syndrome. Some patients respond in a different manner, with fixed airflow obstruction, and in these subjects bronchiolitis obliterans is probably present (see below). It is likely that inflammation of bronchioles is a feature of all patients with persisting symptoms after irritant gas inhalation but that relatively few develop the full-blown obliterative features.

**Smokers' bronchiolitis**

It has long been recognized that cigarette smokers develop inflammation in the bronchioles (Fig. 29.1) as well as in the major airways and alveoli [9,10]; morphometric studies have shown that smokers with airflow obstruction have increased thickness of bronchiolar walls with decreased luminal diameter [11]. At one time it was thought that this lesion might be the primary one leading to the development of airflow obstruction in a proportion of smokers and that early detection by lung function testing might allow targeted treatment. This hope has not been fulfilled, partly because the lung function tests have proved unable to predict reliably the future fall in airway conductance [12,13] and partly because small airway disease is but one aspect of the inflammatory damage wrought by cigarette smoke.

tumours has shown that alveolitis and accumulation of pigmented macrophages in alveoli relate to areas of ground-glass attenuation and that bronchiolitis or bronchiolectasis relates to micronodules [14]. What may be an extreme variant of this pathological condition has been reported as 'respiratory bronchiolitis causing interstitial lung disease', in which heavy smokers develop cough, shortness of breath and diffuse infiltrates on their chest radiographs [15]. Lung function has been reported as showing a primarily restrictive pattern, with only minimal airflow obstruction. Pathologically, the few subjects described have shown pigmented macrophages throughout the acinus, some non-specific alveolar wall thickening and a mild chronic inflammatory cell infiltrate in bronchiolar walls and alveoli with alveolar cell hyperplasia. The condition appears to have had a relatively benign prognosis even when the patient continued smoking.

#### Mineral dust bronchiolitis

As with cigarette smoke, so also chronic inhalation of a wide variety of toxic substances is likely to cause inflammation, *inter alia*, of small airways. Pathologically, the membranous and respiratory bronchioles are the primary site of reaction to inhaled mineral dusts such as coal, quartz and asbestos [16–18] (Fig. 29.2). Physiological evidence of small airways disease has been demonstrated in coal-miners, silica-exposed workers and asbestos workers [19–21], and there has been much argument as to the significance of these lesions in terms of future development of disabling airflow obstruction. An important difficulty in assessing this has been the fact that most such workers smoke as well, while a more academic argument surrounds the attribution of the obstruction to emphysema or small airways narrowing. To the practising chest physi-

cian these matters are of little importance, although they are of relevance for the prevention of occupational disease and become extremely contentious when dust-exposed workers sue their employers for industrial injury compensation. From a preventative point of view, the evidence suggests quite strongly that mineral dust exposure contributes (with cigarette smoking) to the development of this type of physiological impairment, and account should be taken of this in setting dust standards.

#### Diffuse panbronchiolitis

Diffuse panbronchiolitis is a well-defined clinicopathological syndrome occurring not uncommonly among people of Japanese, Chinese and Korean descent, with a possible association with HLA-Bw54 [22,23]. It has been described infrequently in the West [24–26]. The condition occurs predominantly in males over the age of 30, who present with cough, wheeze and sputum production. Chronic sinus infection is a usual accompaniment. The chest radiograph shows diffuse small nodular shadows and high-resolution CT (HRCT) shows small rounded centrilobular lesions with linear shadows extending from them, thickened dilated peripheral airways and evidence of peripheral air trapping [27]. The pathological features are of a diffuse chronic inflammatory reaction in respiratory bronchioles, with lymphocytes, histiocytes and plasma cells extending to peribronchiolar tissues but not to alveoli. There is often ectasia of the terminal membranous bronchiole [22].

The natural history of the disease resembles that of cystic fibrosis, in that recurrent infection with *Haemophilus influenzae* becomes persistent and is succeeded by superinfection with *Pseudomonas aeruginosa*. While rapidly fatal cases occur, the usual course is chronic with gradually

**Fig. 29.2** Lung of rat showing early peribronchiolar fibrotic reaction in response to experimental inhalation of asbestos.

worsening cough, sputum production and increasing breathlessness, leading to death in cardiorespiratory failure. Lung function shows an obstructive pattern with overinflation, leading to reduction in vital capacity and diffusing capacity in the later stages. Untreated, the survival rates at 10 years have been reported as 12% in patients infected with *Pseudomonas* and 73% in those not so infected [28]. The cause of the disease is not known but is presumably related to a genetic impairment of lung defences to the infecting organisms which, once established, cause the pathological lesions [29].

The airflow obstruction in these patients is poorly if at all reversible, and bronchial reactivity is little increased [30]. Nevertheless, 8 weeks of treatment with oxitropium bromide has been shown to decrease airflow obstruction and reduce sputum production in some patients [31]. More importantly, Japanese workers have demonstrated that the prognosis can be substantially improved and symptoms relieved by long-term treatment with low-dose erythromycin (600mg daily), which improves the 10-year survival to better than 90% [28,32]. Other new macrolide antibiotics have also been shown to be of help. It appears that these benefits may accrue, at least in part, from other than direct antibacterial properties of the drugs as a result of interference with both the ability of neutrophils to respond to chemotaxis and the capacity of *Pseudomonas* to produce the biofilm that makes it ineradicable [33–35].

### **Obliterative bronchiolitis**

#### **Aetiological factors**

Obliterative bronchiolitis occasionally occurs without known cause, when it most usually takes the form of the

proliferative type known as BOOP. However, the syndrome does occur rather more frequently, although still rarely, as a response to known causes, the most important of which are shown in Table 29.1. The idiopathic type sometimes follows an influenza-like illness and one suspects that it may sometimes be due to an undetected viral infection [36]. Occasional cases in adults have been described following mycoplasmal or viral infections [5,37–39] and it has been recognized as a complication of human immunodeficiency virus infection [40,41]. A dramatic outbreak in Taiwan in 1996 was caused by consumption of a salad vegetable, *Sauropus androgynus*, either eaten or drunk as a juice. It caused severe impairment in most of the 115 subjects studied and death in seven [42,43]. In infants and children, whose lungs are not fully developed, the condition is usually transient, although permanent damage to bronchioles may occur [44,45]. The development of obliterative bronchiolitis after infection in these circumstances may lead to the maldevelopment of acinar structures with a small avascular and transradiant lung and expiratory air trapping, a condition known as Macleod's or the Swyer–James syndrome [46–48]. This condition is often also associated with bronchiectasis.

Obliterative bronchiolitis may occur after inhalation of a wide range of toxic gases or fumes [49–55]. The classic episode is nitrogen dioxide exposure, although the author has seen it also after acute exposure to chlorine, dimethyl disulphide, hydrochloric acid and several other accidental gassings, as well as (on two occasions) after inhalation of a fine powder of a chlorine-liberating disinfectant. It may therefore be regarded as a possible consequence of exposure to any gas, fume or fine soluble dust with the potential to injure airways either on account of its strongly acidic or alkaline pH or because of its ability to release

toxic free radicals. This latter mechanism may explain the one episode reported following inhalation of fly ash [54], which contains high concentrations of transition metals such as vanadium that are capable of releasing hydroxyl radical by a redox mechanism. It appears to be a relatively rare consequence of such exposures [55], most people recovering with simply transient symptoms or after a period of several months of bronchial hyperreactivity. The episode that leads to it usually appears to be a high-dose exposure associated with symptoms, but this is not always the case and symptoms may develop after what seems to have been a much less severe episode, sometimes unassociated with symptoms.

Bronchiolitis obliterans has been described in all connective tissue disorders, although it is a very infrequent complication in any of them. Rheumatoid disease is the one in which it is most likely to be seen, especially in women [3,56], although it has also been described in Sjögren's syndrome, scleroderma, polymyositis, lupus erythematosus, cryoglobulinaemia and various vasculitic conditions [57–61]. In some cases suspicion has been cast on drugs used to treat the condition, especially penicillamine and gold [58,62]. However, there is no doubt that bronchiolitis can occur in the absence of such treatment. Other drugs that have been associated rarely with development of the syndrome include several cytotoxics, amiodarone, acebutolol, sulfasalazine (sulphasalazine) and overdose of L-tryptophan [63–66]. A spectrum of pulmonary diseases may also be associated with inflammatory bowel disorders, both ulcerative colitis and Crohn's disease, including suppurative bronchitis, bronchiectasis and obliterative bronchiolitis [67] (see Chapter 53).

Bronchiolitis obliterans is now well described in recipients of marrow or lung transplants. In recipients of bone marrow, usually allogeneic but sometimes autologous transplants may lead to graft-versus-host disease in which some 10% develop bronchiolitis [68,69]. In heart–lung transplantation, some 10–70% of recipients develop obliterative bronchiolitis, and a similar risk applies also in single or double lung transplantation [70–72]. The risk relates more to the development of a prolonged rejection reaction, possibly made worse by associated infection, than to the type of transplant [73–75].

In patients with peripheral lung carcinoid tumours, obliterative bronchiolitis has been found in a surprisingly high proportion, 8 of 25 in one study, suggesting that the fibrotic reaction in the small airways was a direct consequence of the tumour [76]. A similar association has been described in one patient with the very rare condition of multiple carcinoid tumourlets [77].

As a footnote to the aetiology, clinicians need to beware of too readily accepting a pathology report of bronchiolitis obliterans as meaning that there is generalized lung disease, since local inflammation and obliteration of small

airways as a consequence of, for example, infection or aspiration is not uncommonly seen in biopsy specimens. As always, biopsy evidence has to be interpreted in the light of the entire clinical picture. Bronchiolitis obliterans is essentially a description of a pathological appearance that has many causes.

### Presenting features

The patient usually presents with dry cough and increasing breathlessness over several weeks or months, and the diagnosis is most easily made in those cases where a predisposing condition such as collagen disease, inflammatory bowel disease or transplantation is present [78]. In idiopathic cases, the condition is most likely after the age of 40. There may be a history of a recent viral type of illness. There may be evidence of a generalized illness in patients with BOOP, with fever, malaise and loss of weight [79–81]. An exposure to inhalation of a toxic substance usually occurs some days or weeks previously; indeed it is usual for any acute symptoms to have settled and for there to have been a period of apparent recovery prior to the development of cough and breathlessness, in contrast to the reactive airways dysfunction syndrome where symptoms usually follow the episode immediately. This period relates to the time taken for obliteration of the small airways to become severe enough to cause noticeable obstruction to overall airflow, as a consequence of their very large total cross-sectional diameter.

The reason bronchiolitis goes unrecognized so often is that there is no distinctive pattern of physical signs [82]. Despite clear evidence of exertional dyspnoea, there may be no signs on auscultation. On the other hand, there may be diffuse gravity-dependent inspiratory crackles, wheezes or both. In idiopathic BOOP, crackles are the most consistent sign, being present in up to 75% of patients. Digital clubbing is not a feature.

The radiographic appearances are also quite variable. It is not uncommon for the chest film to be essentially normal and this should not be regarded as evidence against the diagnosis. Diffuse nodular or ground-glass opacities are common in idiopathic BOOP (Figs 29.3 & 29.4) and a fine interstitial nodularity may be seen in toxic gas exposure. There may be evidence of overinflation. CT may be helpful in showing subtle abnormalities even when the plain film appears normal [83]. For example, in obliterative bronchiolitis without the pneumonitis a mosaic pattern of reduced attenuation on HRCT may indicate air trapping, and expiratory CT has been used to demonstrate this in localized areas [84–86]. In the BOOP syndrome it would be expected that more obvious abnormalities might be seen on CT, reflecting the interstitial component of the disease (Fig. 29.5). Even so, CT studies of histologically diagnosed BOOP have shown a bewildering range of different appearances, including

**Fig. 29.3** Chest radiograph of patient with idiopathic biopsy-proven bronchiolitis obliterans with organizing pneumonia showing diffuse nodular shadows. (Courtesy of Dr Lesley Gomersal.)

**Fig. 29.4** High resolution CT of patient in Fig. 29.3 showing diffuse small centriacinar nodularity. (Courtesy of Dr Lesley Gomersal.)

**Fig. 29.5** High resolution CT of patient with biopsy-proven bronchiolitis obliterans with organizing pneumonia showing patchy irregular consolidation. (Courtesy of Dr Lesley Gomersal.)

consolidation, focal nodular lesions and ground-glass attenuation [87]. As with the physical signs, radiography and CT do not provide a distinctive pattern on which the diagnosis can confidently be made but usually contribute sufficiently to the whole picture to lead to the correct diagnosis.

Lung function tests are usually abnormal in people with symptomatic obstructive bronchiolitis, although again the

findings vary. Impaired exercise tolerance and arterial desaturation are important indicators of severity. In the idiopathic type a restrictive pattern with impaired gas transfer is most common, whereas in those types that follow transplantation or toxic gas inhalation and in collagen diseases severe irreversible airflow obstruction is more frequent. However, either of these, or a mixed pattern, can occur in any of the aetiological types of bronchiolitis.

It can therefore be seen that no one distinctive clinical picture leads to the diagnosis of obliterative bronchiolitis, yet paradoxically the clinical diagnosis is not difficult if one considers the possibility. In the case of someone with predisposing disease, the onset of a persistent dry cough and increasing breathlessness in the absence of other obvious cause such as infection or heart failure should always arouse the suspicion of bronchiolitis. In otherwise previously well people, similar symptoms are usually first thought to be due to asthma or, if the chest film is abnormal, sarcoidosis or a pulmonary arteritis. The clinical features of these diseases differ quite markedly, although in cases of doubt it is usually necessary to test one's suspicion with a lung biopsy.

### Pathology

Two distinct histopathological appearances may contribute to obliterative bronchiolitis [88]. In one, there is constriction of many membranous bronchioles by fibrous tissue in the adventitia and submucosa, a chronic inflammatory cell infiltrate and bronchiolar ectasia distal to the constriction with mucous plugging (Fig. 29.6). The changes are often patchy, and more proximal bronchial inflammation and fibrosis may be associated. This type is called constrictive bronchiolitis obliterans and is the one most characteristically seen in collagen diseases, inflammatory bowel disease and after transplantation, although it may occur as a consequence of all the other aetiological factors. Physiologically it is associated with an irreversible obstructive syndrome. The second type, usually known as proliferative bronchiolitis obliterans, is characterized by organizing connective tissue forming polyps that partially or completely obstruct the lumen of the bronchioles. These polyps contain fibroblasts, foamy macrophages and lymphocytes in loose connective tissue (Fig. 29.7). This type

tends to be more peripheral, sometimes involving respiratory bronchioles and alveoli; in the latter case the extension of the plugs of granulation tissue into the acinus, with some chronic inflammatory cell infiltrate in alveolar walls, allows the pathological diagnosis of BOOP or cryptogenic organizing pneumonitis [4,79]. The former term is preferable, since the condition is primarily a bronchiolar disease and may not be cryptogenic. Alveolar wall fibrosis and honeycombing are not significant features of this condition, in contrast to cryptogenic fibrosing alveolitis. Idiopathic bronchiolitis obliterans is most commonly of the proliferative type, although identical pathological features may be found after viral infections, toxic fume exposure, systemic diseases and transplantation. The physiological abnormality tends towards a more restrictive pattern of lung function.

From the foregoing, it is apparent that the pathological features do not usually help in determining the aetiology of the bronchiolitis, which is established on clinical grounds. However, lung biopsy is helpful in identifying the cause of the functional disorder, in excluding other causes of peripheral lung disease and in pointing towards prognosis, since the proliferative type is far more likely to respond to treatment than the constrictive type.

### Clinical course and management

#### *Idiopathic bronchiolitis obliterans with organizing pneumonia*

Bronchiolitis obliterans with patchy or diffuse infiltrative lesions (BOOP) appears to be the most common adult presentation of bronchiolitis obliterans, being found in 57 of 67 cases of bronchiolitis analysed in Boston, USA [4]. The patients often presented with a history of cough or an

**Fig. 29.6** Section of lung of patient with constrictive bronchiolitis obliterans after heart–lung transplantation showing chronic inflammatory cells and fibrous tissue occluding the bronchiolar lumen (haematoxylin & eosin  $\times 240$ ).

**Fig. 29.7** Section of lung in patient with proliferative type of bronchiolitis obliterans showing obliteration of a respiratory bronchiole by proliferating fibrous tissue (haematoxylin & eosin  $\times 100$ ).

influenza-like illness 4–10 weeks previously. Age at presentation was 40–60 years with an equal sex incidence. Crepitations were audible on auscultation in the majority. The chest radiograph showed a pattern of patchy, often irregular, densities with a ground-glass background appearance in 81%. Unlike patients with bronchiolitis associated with connective tissue diseases, these patients showed evidence of restrictive lung disease in 72%, with a decreased diffusing capacity in 86%. An obstructive pattern was only seen in smokers. The pathology showed plugs of granulation tissue involving bronchiolar and alveolar ducts, with extension of the organization from distal alveolar ducts into alveoli and variable degrees of interstitial infiltration by mononuclear cells, i.e. the pattern of an organizing pneumonia.

The course of the disease is usually (though not always) progressive and may occasionally be fulminant [89,90]. Nevertheless it frequently responds to therapy with corticosteroids in an initial dose of 60–80 mg daily. This dose is continued for 1–3 months, with a graduated reduction thereafter over 6–12 months to a low maintenance dose or to zero. In the Boston series 65% recovered and other authors have reported a good prognosis [91,92].

### ***Toxic gas bronchiolitis***

The characteristic feature of bronchiolitis following exposure to toxic gas or fume is a latent period between exposure and development of symptoms of a few days to several weeks. Thereafter there is progressive increase in shortness of breath over several months followed by stabilization of irreversible airflow obstruction. The condition may be, indeed usually is, preceded by acute symptoms of irritative bronchial disease and is often accompanied by persistent but slowly improving reactive airways dysfunction syndrome. Thus the clinical picture may seem complicated until one realizes that acute airway irritation may

cause several effects at all levels of the airways simultaneously. Since these patients present sporadically with an acute illness it is not surprising that controlled trials of therapy have not been reported. However, based on anecdotal clinical evidence it remains sensible to treat patients with apparently progressing symptoms early with high-dose steroids and to follow their response with lung function tests [49,93–95].

### ***Other aetiological types***

Several aetiological types have rather characteristic clinical courses, although any course may occasionally occur in any type. In those of viral aetiology, the course corresponds to the histopathological type and it seems likely that in some cases the proliferative type may heal by fibrosis and become the constrictive. High-dose steroid therapy is therefore indicated in apparently progressive cases [96]. However, some less severely affected patients show spontaneous resolution without treatment. In the collagen diseases, the constrictive type is more frequent, the course more indolent with a poor prognosis and progression less likely to be arrested by steroids [3]. In contrast, in inflammatory bowel disease steroid responsiveness is more likely. An interesting feature of this condition is the occasional occurrence of lung disease after total colectomy for ulcerative colitis. Transplant-associated bronchiolitis occurs as a consequence of repeated episodes of rejection, and may be prevented by treating patients who have suffered three such episodes by daily nebulized budesonide at a dose of 500  $\mu$ g [97].

In progressive bronchiolitis obliterans, whatever the aetiology, a fatal outcome is possible and in these circumstances there is a case for considering lung transplantation in suitable patients. Paradoxically, this technique has been used most frequently in the management of post-transplant bronchiolitis [98,99].

# CYSTIC FIBROSIS

ANDREW P. GREENING

Cystic fibrosis (CF) is the most common fatal inherited disease in Caucasian populations of European origin. A carrier rate of about 1 in 25 and an autosomal recessive inheritance gives rise to approximately 1 in 2500 children being affected in the UK. The consequent physiological abnormality results in faulty ion transport and water movement across epithelial cells.

Despite the disease being the result of a defect in a single gene that codes for an ion channel, there are many differences in clinical expression. Abnormality of transport of chloride and sodium ions across some epithelia is an essential feature. The respiratory tract and the pancreas are the organs that bear the predominant burden of disease, with some 80% of patients having both recurrent pulmonary infections and pancreatic insufficiency. About 15% of patients have apparently normal pancreatic function but have lung disease and some 5% have gastrointestinal problems but no overt respiratory manifestation. Clinical presentation is usually at birth, with meconium ileus, or early childhood, with recurrent respiratory infections and/or failure to thrive. However, some patients with milder variants of the disorder may present later in life, when the diagnosis may be much less obvious.

## Historical review

The disease may have been recognized in folklore [1]. In old European cleansing ceremonies it was customary to lick the forehead of newborn infants. The child was feared 'bewitched' and soon to die if it tasted salty. In 1938, Dorothy Andersen in New York is credited with the first formal description of CF as a separate pancreatic pathological and clinical entity, differentiating it from coeliac disease [2]. Blackfan and May [3] reported similar findings from Boston in the same year and Blackfan and Wolbach [4] had published analogous cases in 1933 without specifically naming a 'new' disorder. In 1936, Fanconi and colleagues [5] had also identified a consistent relationship between congenital pancreatic cystic fibromatosis and bronchiectasis, which proved later to be compatible with

CF. Farber [6] introduced the term 'mucoviscidosis' in 1943 following studies which suggested that all exocrine glands had evidence of pathological changes. A high incidence of heat prostration was observed among CF patients during a New York heatwave in 1948, attracting di Sant'Agnese and colleagues [7] to study patients' sweat. They showed the sodium and chloride levels to be elevated and this formed the basis of the subsequent sweat test as the diagnostic procedure for CF; indeed it has remained the cornerstone of diagnosis to the present day. Initially this was carried out by warming the patient to produce sweating but in 1959 a test was introduced whereby sweat was induced by the iontophoresis of pilocarpine [8], which is reproducible and avoids the possible risks of heat prostration.

The autosomal recessive nature of inheritance was first suggested by Andersen and Hodges in 1946 [9] and established in the 1960s [10]. The gene was localized to the long arm of chromosome 7 in 1985 [11,12] and isolated in 1989 [13–15]. Such is the pace of current applied molecular biology that the first trial of gene therapy for CF in humans was published only 4 years later [16]. Studies of the gene product, the cystic fibrosis transmembrane conductance regulator (CFTR), have advanced the understanding of the pathogenetic processes and revealed potential new therapies. Molecular analyses of CF genotypes have taken the history of the disease full circle and helped trace its evolutionary path. Haplotype analysis of chromosomes carrying the CF mutation from different geographical regions has suggested that the most common mutation probably first occurred over 52000 years ago during the palaeolithic era [17] in a population that migrated into Europe. It has been estimated that no lethal recessive disorder could reach the high frequency that CF has in Europe just by genetic drift. Heterozygous advantage (sickle cell disease [18], cholera [19], gastroenteritis and tuberculosis [20]) or increased fertility among CF carriers [21] have therefore been postulated. Protection against gastrointestinal disorders is an empirically attractive hypothesis and supported by recent work. A thermostable

enterotoxin from *Escherichia coli* induces chloride secretion only in cells with normal CFTR, which could give a CF heterozygous person advantage for *E. coli* diarrhoea [22]. In addition, CF heterozygous mice may show resistance to cholera toxin [23].

## Genetics

### CF gene and CFTR

The CF gene is large, comprising 27 exons [24] and encompassing approximately 250kb of genomic DNA. This encodes a mature mRNA of 6.5kb [13] that codes for a protein, CFTR, with a molecular mass of approximately 168kDa [14]. There are two hydrophobic membrane-spanning domains, two regions that bind ATP and a regulatory domain containing multiple sites for phosphorylation by protein kinases A and C [14] (Fig. 30.1). This overall structure is similar to a large family of proteins

that transports molecules into or out of cells in an ATP-dependent fashion [25]. One of these is the human multiple-drug resistance protein, which confers resistance to cancer chemotherapy by exporting drugs from cells. However, despite the similarities, CFTR does not appear to function as an ATP-dependent transporter but as a cyclic AMP-activated chloride channel [26–30]. Cross-species analyses show marked structural conservation between the human CFTR and its bovine, mouse, rat and dogshark homologues [31–34] (90% human to cow; 76% human to mouse), with 95–100% homology in some regions. These cross-species studies suggest that the function of CFTR may be similar in evolutionarily very diverse organisms.

### CFTR promoter

The sequence of the CFTR promoter region has been determined. The structure has led to the proposition that the

**Fig. 30.1** (a) Diagrammatic representation of the structure of the cystic fibrosis transmembrane conductance regulator (CFTR) showing two transmembrane regions, two domains that bind with ATP (nucleotide-binding domains) and a regulatory domain that has multiple sites for phosphorylation by protein kinases A and C. (Adapted from Riordan *et al.* [14].) (b) Schematic representation of CFTR and the corresponding exons of the gene.

CFTR gene may belong to a group of genes that have been characterized as 'housekeeping' genes that in addition have tissue-specific functions [35]. For example, like housekeeping genes the CFTR gene contains no TATA or CAAT box element. However, there are sequences that suggest it could be under transcriptional regulation. Potential AP-1 and AP-2 binding sites have been identified, as well as candidate sequences for cyclic AMP and glucocorticoid response elements [36].

### CFTR function

CFTR appears to have additional functions to those of a chloride channel in the apical membrane of epithelial cells. Endocytosis and exocytosis are defective in a CF pancreatic cell line, although this is corrected by the expression of wild-type CFTR [37]. It has also been proposed that in CF there is a defect in the acidification of the trans-Golgi network, of prelysosomes and of endosomes because of diminished chloride conductance in the membrane of these intracellular organelles [38].

In addition, there is a considerable amount of evidence that expression, and probably activity, of CFTR is capable of modulating the function of other ion channels in epithelial cells [39]. A separate chloride channel, the outward rectifying chloride channel (ORCC), has been shown to have a regulatory relationship with CFTR [40,41]. It is uncertain whether this involves direct protein-protein interactions [42], interaction through cytoskeletal elements [43] or activation of ORCC via a purinergic receptor [44] involving CFTR-mediated release of ATP from cells [45,46]. Early work had shown a consistently elevated and abnormally regulated sodium absorption in CF airway epithelia [47]. It is now recognized that these observations reflect an absence in CF cells of negative regulation of sodium channels by CFTR [48,49]. The nature of the interaction between CFTR and this epithelial sodium channel is unclear. However, the epithelial sodium channel has a two to three fold higher probability of being open in the CF cell and hence the increased sodium absorption.

### CFTR expression

CFTR RNA is expressed in epithelial tissues classically affected in CF, such as the lung, pancreas, liver and sweat glands [14] but also large intestine, testis [50,51] and kidney (Table 30.1). RNA studies indicate a low level of CFTR transcripts in respiratory epithelium and much higher levels in the pancreas and intestine [50,52] and in the airway submucosal glands [53].

### CF gene mutations and effects on CFTR

More than 600 mutations of the gene have now been rec-

**Table 30.1** Tissue and cellular localization of CFTR.

Organ localization	Cells	Cellular
Airways	Ciliated epithelium Submucous glands	Apical membrane Intracytoplasmic
Pancreas	Ductal epithelium	Apical membrane
Liver	Bile duct epithelium	Apical membrane
Sweat glands	Reabsorptive duct epithelium	Apical and basolateral membranes
Intestine	Basal cells of crypts	Apical membrane
Kidneys	Collecting tubules	Apical membrane

ognized, although the frequency of the different abnormalities is very unevenly distributed and varies between geographical regions [54–56]. The most common mutation, a deletion of three nucleotides in exon 10 resulting in the omission of a single amino acid, phenylalanine, at residue 508 (termed  $\Delta F508$ ), accounts for 68% of CF alleles worldwide, reported to the CF Genetic Analysis Consortium [54], and just over 70% in the UK and other parts of northern Europe. Only 13 mutations reported to the Consortium have a frequency of greater than 1% (Table 30.2) but these account for approximately 85% of all CF alleles. The majority of the rest occur infrequently, although again with significant geographical variation [57] and many in single families.

### Mutations that alter CFTR mRNA

About half the mutations reported to the Consortium are predicted to affect RNA processing. These can be divided into two groups: those that introduce a premature signal for the termination of translation and those that alter the mRNA but leave the reading frame intact. The former group includes changes in a single nucleotide that substitute an amino acid with a termination signal (nonsense mutation), deletion or insertion of one, two or more nucleotides that are not multiples of three (frameshift mutation), or abnormal exon splicing (splice-site mutation).

### Nonsense mutations

The most common outcome of these mutations is a severe reduction of mRNA levels from the gene containing the alteration. The RNA is produced in normal amounts but is not transported out of the nucleus into the rough endoplasmic reticulum for translation [58]. Examples of this type of mutation include G542X, R553X and W1282X [59–61]. Severe reduction in mRNA transcripts should cause reduction or absence of CFTR protein and this appears to be the case [62] (Fig. 30.2).

**Table 30.2** CFTR gene mutations reported to the Cystic Fibrosis Genetic Analysis Consortium [54] with a relative frequency of >1%.

	Relative frequency	Mutation	Consequence
ΔF508	67.2	Deletion of 3 bp between nt 1652 and 1655 in exon 10	Deletion of Phe at codon 508
G542X	3.4	G→T at nt 1756 in exon 11	Gly→Stop at codon 542
G551D	2.4	G→A at nt 1784 in exon 11	Gly→Asp at codon 552
W1282X	2.1	G→A at nt 3987 in exon 20	Trp→Stop at codon 1282
3905insT	2.1	Insertion of T after nt 3905 in exon 20	Frameshift
N1303K	1.8	C→G at nt 4041 in exon 21	Asn→Lys at codon 1303
3849+10 kbC→C	1.4	C→T in a 6.2 kb <i>Eco</i> RI fragment 10 kb from 5' junction on intron 19	Aberrant splicing
R553X	1.3	C→T at nt 1789 in exon 11	Arg→Stop at codon 553
621+G→T	1.3	G→T at nt 1 from 5' junction of intron 4	Splice mutation
1717-1G→A	1.1	G→A at nt 1 from 3' junction of intron 10	Splice mutation
1078delT	1.1	Deletion of T at nt 1078 in exon 7	Frameshift
2789+5G→A	1.1	G→A at 5 nt from 5' end of intron 14b	Splice mutation
3849+4A→G	1.0	A→G at 4 nt from 5' end of intron 19	Splice mutation

nt, nucleotide.

**Fig. 30.2** Effects of the five classes of mutation of the cystic fibrosis transmembrane conductance regulator (CFTR) and the sites influencing CFTR synthesis, processing and function.

**Splice-site mutations**

The effects of splice-site mutations are more difficult to predict. Two examples, 621+1G→T and 711+1G→T, account for 1.3% and 0.9% of mutant CF alleles respectively [56]. The former mutation alters the splice site immediately following exon 4 and produces two aberrantly spliced RNAs, both of which retain an open reading frame [63,64]. The latter mutation changes the splice site following exon 5, causing skipping of the entire exon, but since the number of nucleotides here is a multiple of three the reading frame is left intact [40]. It can be predicted that these aberrant transcripts will be translated into protein products that may be unstable, non-

functionally active, or both. The former mutation produces two aberrantly spliced RNAs, both of which retain an open reading frame [63,64]. The latter mutation changes the splice site following exon 5, causing skipping of the entire exon, but since the number of nucleotides here is a multiple of three the reading frame is left intact [40]. It can be predicted that these aberrant transcripts will be translated into protein products that may be unstable, non-

functional or partially functional. Determining which of these possibilities occurs usually requires protein expression and analysis.

A putative disease-associated mutation was discovered that should lead to a CFTR mRNA transcript missing exon 9 [65]. This would be expected to produce non-functional protein because exon 9 encodes a critical region of the first ATP-binding domain. However, exon 9 is missing from a significant fraction of CFTR mRNA transcripts in most normal individuals [66]. The length of a polypyrimidine tract upstream of the 3' splice acceptor site within intron 8 appears critical [67] for the splicing efficiency of exon 9 (Fig. 30.3). An optimal splice acceptor site lies downstream of 11 consecutive cytosines or thymidines [68]. In intron 8 of the CFTR gene this tract exists in three polymorphisms, consisting of five, seven or nine thymidines [69]. Consequently, the longest tract length, 9T, results in the most efficient splice acceptor, producing over 95% of CFTR transcripts with exon 9 intact. The 7T tract results in 50–90% intact transcript, but the 5T tract is inefficient and produces as little as 5% per allele [68,69]. This allows for some individuals to display variant clinical CF if they have a mutant CF allele and their 'normal' allele carries

the inefficient 5T variant or if they are homozygous for the 5T allele. Under such circumstances very little functional CFTR protein may be produced, possibly under 10% [60,61,67].

### Mutations and abnormal CFTR processing and trafficking or chloride channel function

Early investigations showed that CFTR bearing the common  $\Delta F508$  mutation was incompletely glycosylated, suggesting that it was incompletely processed and not transferred to the cell membrane [70] (see Fig. 30.2). Also it appears to be temperature sensitive [71], and at lower temperatures can traffic to the cell membrane [72,73] where it has reasonable function as a cyclic AMP-dependent chloride channel [74]. Other mutations traffic to the cell membrane under normal circumstances, for example the relatively common (3% worldwide) allele G551D [75], where they display impaired function. Welsh and Smith [76] have reviewed these. At least two categories appear to exist (see Fig. 30.2). Mutations may impair the activation of CFTR; these occur in the ATP-binding domains and may respond to high levels of stimulation [77]. Other mutations alter the conduction properties of the CFTR chloride channel. Three such mutations (R117H, R334W, R347P) have been reported to be associated with milder disease and the CFTR channel appears partially functional [78–80].

### CF gene mutations and patient phenotype

CFTR mutations can be grouped into five classes, as indicated above, on the basis of CFTR protein alterations (see Fig. 30.2): class I, no synthesis; class II, block in processing; class III, block in regulation; class IV, altered conductance; class V, reduced synthesis. CF shows markedly variable clinical features. Although some of these may be explained by differences in CFTR mutation, the majority show no clear relationship. On examining the common  $\Delta F508$  mutation, while there appears almost complete association with pancreatic status and sweat chloride concentrations, the pulmonary disease varies from extremely mild to very severe [81,82]. Pancreatic function does appear more closely related to the specific mutation carried, and mutations associated with exocrine pancreatic sufficiency (PS) are dominant to those associated with pancreatic insufficiency (PI) [83]. An early report linked mild disease and PS [78] and, by and large, this observation holds. A more extensive assessment of over 500 patients attending a single clinic identified five mutations (R117H, A455E, R334W, R347P and P574H) found exclusively in pancreatic sufficient patients [83]. However, the PS phenotype and genotype relationship is not absolute. In the large genotype-phenotype Consortium analysis [82], 10 of 396  $\Delta F508$  homozygotes were pancreatic

**Fig. 30.3** (a) A section of the cystic fibrosis transmembrane conductance regulator (CFTR) gene. During processing, introns (sequences not involved with protein synthesis) are eliminated and the remaining sequences, exons, are spliced to form mature mRNA. DNA variations in intron 8 affect splicing efficiency and lead to different proportions of mRNA missing exon 9. (b) The relative percentage of normal CFTR depends on the number of thymines in the polyT sequence in intron 8, and the pairing of 9T, 7T and 5T alleles.

sufficient and 3 of 23 R117H/ $\Delta$ F508 compound heterozygotes were pancreatic insufficient.

In CF, more than 95% of men are azoospermic because of congenital bilateral absence of vas deferens.  $\Delta$ F508 mutation in men with this lesion is about 0.5 as opposed to the 0.03 in the general population [84]. A number of these men carry a second CF mutation and many who appear to have only one detectable CF mutation are also carriers of the 5T exon 9 splice variant on the other chromosome [85]. The association of specific organ involvement with specific CFTR mutations allows speculation that there exists a hierarchy of organ sensitivity to deficits in functional CFTR.

## Ion transport

The evolving knowledge of CFTR function in ion transport provides a physiological basis for the more long-standing recognition of chloride, sodium and water abnormalities involving the sweat glands, airways, intestine and the pancreatic and biliary ducts. The disordered ion transport and water movement in these tissues is the basic abnormality leading to the pathophysiological consequences.

## Sweat glands

While the abnormal sweat is only of clinical consequence in a hot environment, it has provided the basis of the 'gold standard' diagnostic test for CF for over 30 years. Sweat is formed from an electrolyte solution secreted into the secretory coil and is isotonic with plasma. It is modified as it passes through the duct by absorption of chloride and sodium. In CF the volume and rate of sweat production are normal [86], as is the composition of the primary secretion, but the reabsorption of ions is reduced because the ductal cells are impermeable to chloride and sodium ions are secondarily retained by the negative charge of the chloride ions. The sweat reaching the skin has a high sodium (~80 mmol/L) and chloride (~100 mmol/L) content and the duct lumen has a high negative charge [86].

However, other abnormalities of CF sweat glands are not so readily explained. Vasoactive intestinal peptide innervation is markedly reduced in comparison to normal tissues [87] and the role of prolactin in sweat formation may be altered in CF glands [88].

## Airways epithelium

Cilia on airway cells beat within an aqueous environment, the 'sol'. This fluid is thought to be generated predominantly in the periphery of the lung and moved cranially by ciliary beating [89]. The alveolar surface volume is vastly greater than the airway surface volume, and if the hypoth-

esis is correct the airway epithelial cells must be predominant reabsorbers of the fluid. As in the sweat duct cells, sodium is absorbed through sodium channels in the apical membrane and transported out through the basolateral membrane by the sodium-potassium ATPase [90]. Water follows by osmosis. This sodium and water absorption is probably important for limiting the volume of the periciliary fluid layer.

Obversely, ion transport mechanisms also exist to rehydrate the airway surface. The relatively low intracellular concentration of sodium allows sodium to enter the cell from the basolateral surface via a sodium-potassium-chloride cotransporter (Fig. 30.4). Chloride is thus able to enter the cell and exits, down a gradient, via chloride channels in the apical surface. Water follows the movement of chloride, allowing hydration of the cell surface. Under basal conditions, sodium and water absorption predominate but at times of potential airway dehydration, such as exercise, chloride secretion can be activated to maintain the periciliary fluid volume.

As discussed above, CFTR is a cyclic AMP-dependent chloride channel and modulates the epithelial sodium channel and the ORCC. The consequence of an abnormal CFTR in the airway epithelium is therefore excessive inward sodium and water movement and impaired outward chloride and water movement. This gives rise to a relative dehydration of the pericellular environment, which is believed to contribute to bacterial adherence and colonization. It also leads to an increased (more negative)

**Fig. 30.4** Hydration of the mucosal cell surface depends upon interrelationships between the cystic fibrosis transmembrane conductance regulator (CFTR), the outward rectifying chloride channel (ORCC) and the epithelial sodium channel (ENaC) on the mucosal surface of the epithelial cell and the sodium-potassium ATPase cotransporter and the sodium-potassium-chloride cotransporter on the serosal surface of the cell (see text).

transepithelial potential difference. This change is also seen in the upper respiratory tract, where it is easier to make a measure of potential difference. This valuable observation was first made in 1981 [91], with subsequent research and proposal that nasal potential difference could be used as a diagnostic test [92–97]. As with the sweat test, however, patients with milder clinical disease, presumably with some preservation of CFTR function or alternative channel function, may yield equivocal rather than abnormal results [98].

### Submucosal glands

CFTR is present in the submucosal glands, probably in greater amounts than in the airway epithelium [99]. Cyclic AMP-stimulated chloride secretion is defective [100,101] but there are conflicting data on calcium-stimulated chloride transport [101,102] and no data on sodium transport. The likelihood is that there is reduced mucin output and altered composition of mucus. It is unclear how important such abnormalities may be in the pathophysiological processes.

### Gastrointestinal tract

There are conflicting data on basal chloride conductance [103–105] and amiloride effects on sodium transport [104–107]. However, cyclic AMP-induced chloride secretion has been reported abnormal in the jejunum [108,109], small intestine and colon [110], and rectum [105,106,111]. The combined effect of the abnormalities of ion transport appears to contribute to the development of meconium ileus and the distal intestinal obstruction syndrome. Gastric juices appear to have decreased volume, and increased viscosity and sodium levels [112]. Whether this is related to the increased frequency of gastro-oesophageal reflux is not clear.

### Pancreas

Less is known about pancreatic abnormalities. *In vivo*, in response to infusion with secretin and cholecystokinin, the CF pancreas produces lower than normal chloride, sodium, potassium and bicarbonate [113–115]. The fluid secretion is lower but in proportion to the chloride and bicarbonate levels, suggesting that this is a secondary event [114]. CFTR appears localized principally to the proximal pancreatic ducts, with little at acinar level [116]. This supports the proposition that the pancreatic defect is principally of electrolyte and water secretion rather than pancreatic enzyme production.

### Other tissues

B and T lymphocytes express CFTR and have abnormal

chloride transport [117]. However, this does not appear to yield a functional defect. CFTR is also expressed in the kidney but similarly renal function appears normal.

## Epidemiology

### Incidence

CF is found in all racial groups, although the frequency varies markedly. Reported frequencies in different populations are an underestimate. Neonatal screening does not occur widely and any molecular screening of necessity only examines a limited number of genotypes. As an increasing number of genotypes are recognized, patients with much milder variant disease are identified but will have been 'missed' from population screens.

Large population studies have been reported from Sweden [118], the former Czechoslovakia [119], The Netherlands [120], the USA [121], Ireland [122] and the UK [123], and other smaller reports provide additional information. The data are summarized in Table 30.3. These large population studies have been based on case finding rather than screening. The Swedish study of births from 1950 to 1957 found an incidence of 1 in 7700 [118], the Czechoslovakian study 1 in 5200 [119] and the Dutch study 1 in 3600 [120]. The more recent data from the American CF Registry estimates an incidence of 1 in 3500 live births for whites [121], although much lower incidences for other racial groupings (1 in 10500 for American Indians, 1 in 14000 for Blacks and 1 in 25500 for Asians). The Irish and recent UK surveys give commoner frequencies, 1 in 1461 [122] and 1 in 2415 [123] births respectively.

### Survival

In the 1930s most affected children died in the first few years of life. The prognosis has improved spectacularly since then, with a continuing worldwide increase in

**Table 30.3** Estimated frequency of cystic fibrosis, at birth, in different populations.

National group	Birth incidence	Reference
UK	1/2500	Dodge <i>et al.</i> [123]
USA (white)	1/3500	Fitzsimmons [121]
USA (Black)	1/14000	Fitzsimmons [121]
USA (Asian)	1/25500	Fitzsimmons [121]
Sweden	1/7700	Selander [118]
Former Czechoslovakia	1/5200	Brunechy [119]
The Netherlands	1/3600	Ten Kate [120]
Ireland	1/1500	Cashman <i>et al.</i> [122]
Finland	1/25000	Kere <i>et al.</i> [124]
Israel (Ashkenazi Jews)	1/3300	Kerem <i>et al.</i> [125]
Japan	1/323000	Imaizumi [126]
Faroe Islands	1/1800	Schwartz <i>et al.</i> [127]

survival rates. In the USA, the median survival in 1969 was only 14 years but rose to 21 years in 1978 and 28 years in 1990 [121]. In the UK, the median survival was 31 years in 1994 [123] (Fig. 30.5), although estimates taking into account rates of improvement have suggested that patients born in the 1990s will survive beyond 40 years [128]. The survival of 3-year cohorts for males and females is shown in Fig. 30.6. It is clear that the reduction of mortality in the first year of life, caused principally by meconium ileus, has made a major contribution to the improved survival rates. Other factors, almost certainly antibiotic therapy and probably better nutrition, have effected the improvements beyond the first year, revealed by the progressive change in slopes of the cohort curves.

There are wide ranges in clinical severity of CF, which are reflected in the mortality rates. Genetic and environmental factors probably contribute. Although some genotypes appear to have a better prognosis, the relationship between genotype and phenotype is obtuse, with only a weak but favourable effect of pancreatic sufficiency.

Clinical decision-making may require a reasonable estimate of likely short-term to medium-term survival. Some studies have shown that a range of clinical variables may have such a predictive value [129–134], including infection with *Burkholderia* (*Pseudomonas*) *cepacia*, low weight [129–131], poor lung function [132], short stature and chronic liver disease [134], all of which may be associated with poorer prognosis.

### Clinical presentation and morbidity

The majority of patients present in the first year of life (70% in the 1990 USA registry), although some patients are diagnosed later in life. The same registry indicated that 10% had not been diagnosed by 12 years. Some of the patients with much milder, variant disease escape diagnosis until their thirties or forties, although at times this is because the diagnosis had not previously been consid-

**Fig. 30.5** Survival of UK residents with cystic fibrosis for both sexes for 1994. Median survival is 31 years. (Adapted from Dodge *et al.* [123].)

ered. Most patients present with the symptoms one would anticipate: the USA registry reported that meconium ileus was present at birth in 16%, and that 45% had acute or persistent respiratory problems, 36% failure to thrive and malnutrition, and 21% steatorrhoea and malabsorption at presentation.

Morbidity is a more difficult parameter to assess readily on a population basis. However, the height and weight of CF patients are simple indicators of the effectiveness of treatment. Recent data of over 3000 patients from 31 CF centres in the UK show improvement over earlier published observations [135]. Thus, during the first decade of life the height and weight of patients are now maintained at about 0.5 standard deviations below those of the general population, although they then show a progressive decline (Fig. 30.7).

## Childhood presentations

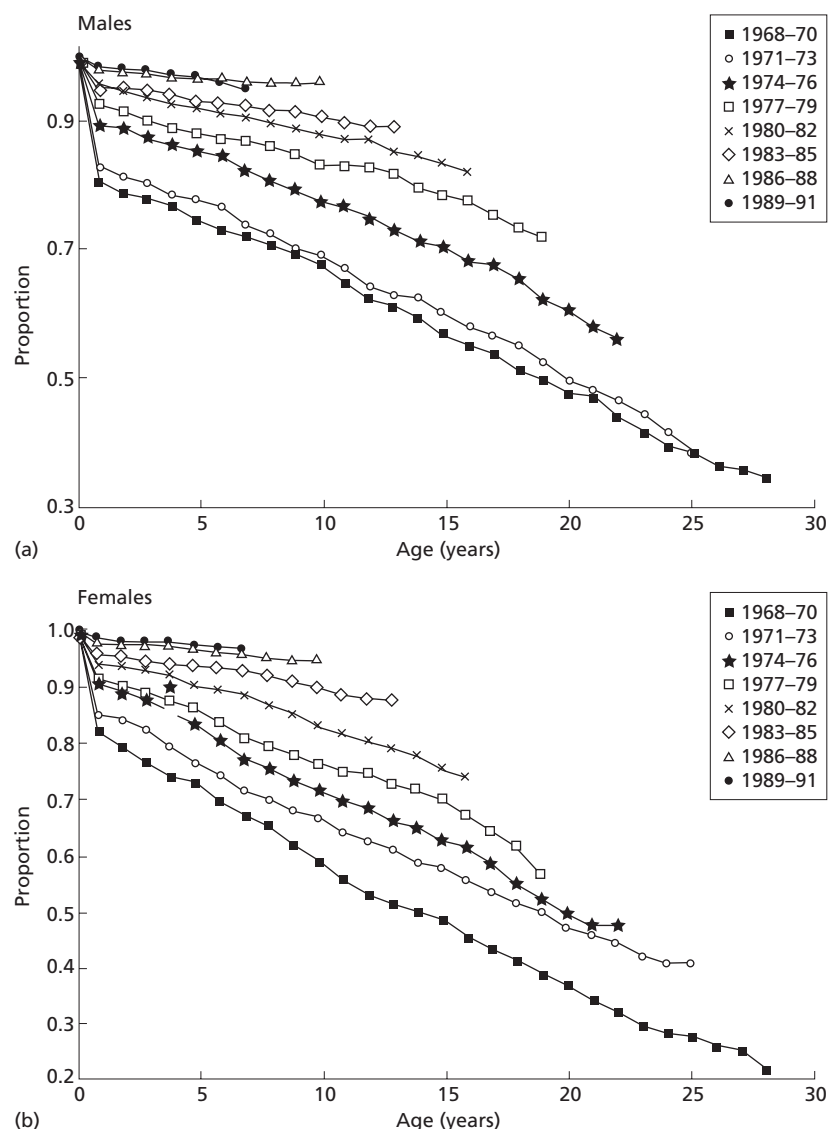

### Meconium ileus

Meconium ileus presents as intestinal obstruction in the neonatal period in up to 16% of children [121], although it may be diagnosed *in utero* at routine ultrasound scanning during the first trimester. The neonatal clinical features are abdominal distension, failure to pass meconium and bile-stained vomiting. Opacification of the right lower abdomen and distended loops of small bowel in the left hypochondrium are seen on radiographs. Calcification may also be seen as small specks or more extensive curvilinear areas. In one study, calcification was seen radiologically in 26% of cases of meconium ileus but identified histologically in 37% of the resected specimens, with the majority being intramural rather than serosal or luminal [138].

The obstruction is due to impaction of inspissated fetal meconium, usually occurring at the ileocaecal junction and extending proximally but sometimes found also in the ascending colon. It is associated with volvulus, ileal atresia or perforation in over 50% of cases. Rarely, a Gastrografin enema may relieve the obstruction [139] but surgery is required in the vast majority of cases. This often includes resection of a non-viable segment of ileum, usually with primary anastomosis. Improvements in the management of this complication of CF have made a major contribution to the improved survival rates.

The pathogenesis of meconium ileus is not fully elucidated. The bowel electrolyte and water transport abnormalities appear to provide the basic mechanisms. The G551D genotype, which is associated with greater apical membrane expression of CFTR than  $\Delta F508$ , has a lower frequency of meconium ileus [140,141]. Pancreatic function has a less clear influence, with the severity of pancreatic insufficiency being no greater in affected individuals than in many other CF neonates. Indeed, meconium

**Fig. 30.6** Survival in successive 3-year cohorts of UK residents with cystic fibrosis: (a) males; (b) females. (Adapted from Dodge *et al.* [123].)

ileus can occur in infants who are pancreatic sufficient [142].

### Prolonged neonatal jaundice

Prolonged cholestatic jaundice in the neonate may suggest a diagnosis of CF [143]. It is present in about 50% of patients presenting with meconium ileus.

### Failure to thrive

Pancreatic insufficiency should be obvious by age 6 months in 75–80% of individuals [144]. In the absence of respiratory infections the affected infants usually have a voracious appetite but gain weight poorly. Usually the child is underweight and has obvious gaseous distension of the abdomen [145]. The stool may be frequent, bulky and offensive. In about 20% there is associated rectal

prolapse, which may be the presenting clinical problem and can be recurrent [146–149]. Rarer associated presentations include anaemia, hypoproteinaemic oedema and hypochloraemic alkalosis [150].

### Recurrent infections

Respiratory symptoms have a variable age of onset and there is no clear marker for those who present early or late. A persistent cough is usually the first symptom. This is often exacerbated by viral infections and sputum appears loose. However, sputum production is uncommon in infants and young children, who tend to swallow the excessive mucus. A historical assessment from Australia (1955–78) showed that 37% of children presented with respiratory infections [151]. More recent data from the USA give a figure of 45% [121]. Wheezing is common, with up to 50% of cases being affected in some centres [152], and

**Fig. 30.7** (a) Mean weight, height and body mass index by age in patients with cystic fibrosis expressed as SD scores relative to the British 1990 growth reference [136,137]: (a) males; (b) females. (Adapted from Morison *et al.* [135].)

there is a risk that the infant may be misdiagnosed as asthmatic.

### Nasal polyps and sinusitis

Nasal polyps are rare in the infant but increasingly common in preschool and school-age children. Presentation is most common between 5 and 14 years [153]. Polyps recur frequently and rapid growth may be a feature. Occasionally, they may be the only presenting feature of CF. There is a common association between sinusitis and nasal polyposis. Although the sinuses are rarely tender to palpation, over 90% are opacified radiographically [154].

### Neonatal screening

Neonatal screening programmes have allowed the early recognition of CF, before any symptoms may have devel-

oped. Screening programmes and benefits of earlier diagnosis are discussed separately.

## Diagnosis

### Sweat test

The sweat test remains the gold standard for diagnosis, although all methods are uncertain at times. The Gibson and Cooke test of 1959 [8] has stood the test of time well and been examined in detail [155,156]. Sweat is stimulated by pilocarpine iontophoresis (a weak electric current aids the penetration of pilocarpine into the skin) and collected on preweighed filters. At least 100 mg of sweat should be analysed for sodium and chloride. Chloride is more discriminative than sodium and sodium values alone should not be used to diagnose CF [157,158]. It is probably correct to regard ion concentrations of greater than 70 mmol/L for both ions as definitely abnormal and indicative of CF, con-

centrations of less than 50 mmol/L as normal, and values of 50–70 mmol/L as equivocal requiring further consideration [158]. Sweat potassium concentrations are also raised in CF but there is some overlap with normal children. The data reported by Shwachman and colleagues [159] from 252 CF children and controls demonstrate these points (Table 30.4).

The sweat test is a complex procedure and there is room for misdiagnosis [160,161]. A single positive test should always be confirmed by a repeat test or with genotyping. The test should be performed by staff and a laboratory that carry out sweat tests on a frequent basis, not just occasionally. Infants under 4 weeks of age or 3 kg tend to produce too little sweat, and dry skin at any age is a problem. Thus eczema, with a small sweat volume, is a relatively common reason for raised electrolyte values. There are a number of rare conditions that may also cause raised sweat electrolytes: adrenal insufficiency, ectodermal dysplasia, hypothyroidism, familial hypoparathyroidism, nephrogenic diabetes insipidus, glucose 6-phosphatase deficiency, mucopolysaccharidoses, glycogen storage disease type I, anorexia nervosa and severe malnutrition.

Sweat sodium and chloride do show some variation with age; normal teenagers and young adults may have sweat test values, especially for sodium, that are just within the CF range. The effect of pretreatment with fludrocortisone increases the discriminating power of the sweat test in adults [162], since CF patients are relatively more resistant to its suppression of sweat electrolytes.

### Nasal potential difference

If patients have an equivocal sweat test and the full genotype cannot be defined readily, it is worth while measuring the nasal potential difference [95–97], although the technique is difficult to apply in small infants and equivocal sweat tests often mean equivocal nasal potential difference.

### Tests of pancreatic function

A variety of tests of pancreatic function have been

described for patients with CF [163]. A simple screening test has been to look for fat globules in a stool preparation using a microscope. However, this is not specific for CF and false negatives occur. The gold standard is estimation of total faecal fat in stool collected over 3–5 days, a test designed to endear itself to patients, parents and laboratory staff! The daily dietary fat intake over the period must be adequate: 3 g/kg for infants and 30–100 g for older children and adults. Laboratory methods depend on whether medium-chain triglycerides are included in the diet [164,165]. Normal values for daily faecal fat excretion are usually less than 5 g and often less than 3 g [166].

Searches have been made for more pleasant tests. Faecal chymotrypsin concentrations have been suggested as an indicator of pancreatic exocrine insufficiency in neonates and older children [167,168]. The investigators have recommended testing three random specimens and calculating the mean value. Another alternative, the steatocrit test, examines small amounts of homogenized stool sealed into capillary tubes and centrifuged. The fat content is assessed in the resultant layers (basal solid layer, intermediate liquid layer, upper fatty layer) as the ratio of fatty layer to solid plus fatty layers, expressed as a percentage. However, there have been conflicting views of the reliability of this test [169,170].

Two urinary tests have been devised. They are based on the ability of pancreatic enzymes to cleave a compound administered orally, releasing a product that is absorbed from the gut, conjugated in the liver and excreted in the urine. *N*-benzoyl-1-tyrosyl *p*-aminobenzoic acid (NBT-PABA) releases PABA when acted upon by pancreatic chymotrypsin. PABA is then measured in the urine. However, PABA may not be fully absorbed and so a second collection is made after administration of free PABA, allowing a correction to be applied. This test gives incomplete separation between subjects with pancreatic insufficiency and normal function [171]. The pancreolauryl test is similar. On day 1 fluorescein dilaurate is given and hydrolysed to a variable degree by pancreatic arylesterases, with release of fluorescein. Fluorescein alone is given on day 3 and the overall result expressed as a ratio of the two. The test was reported as 97.6% specific for pancreatic insufficiency, and superior to an estimation of faecal chymotrypsin, in a

**Table 30.4** Sweat sodium, chloride and potassium concentrations (mmol/L) for 252 patients with cystic fibrosis (CF) and 252 controls. (Adapted from Shwachman & Mahmoodian [159].)

	CF patients			Control subjects		
	Sodium	Chloride	Potassium	Sodium	Chloride	Potassium
Mean	111.2	115.3	22.9	28.2	28.0	10.3
SD	12.0	12.1	2.5	6.1	6.0	2.4
Minimum	75.4	78.6	13.8	15.9	7.7	6.0
Maximum	144.6	148.2	29.6	45.9	43.4	16.9

variety of patients not including those with CF [172]. It has distinguished between CF children with 'severe' insufficiency and controls [173]. The newest test measures pancreatic elastase in a 'spot' sample of stool. If it proves to give a true quantitative assessment of pancreatic insufficiency, it will be a welcome advance.

### Genetic tests

The use of the polymerase chain reaction allows genotyping on blood spots or mouth rinses. This can be an useful adjunct to other diagnostic tests and to screening programmes. The large number of variants (>600) means that not all genotypes can be tested, although screening for approximately 20 genotypes would encompass 90–95% of all CF genes within discrete geographical populations. Nevertheless, the costs and the logistical effort involved in screening for more than a very small number of genotypes means that at present genetic tests for a diagnosis of CF are complementary to the other methods described.

### Screening

The potential for neonatal screening was realized following the description of increased immunoreactive trypsin (IRT) levels in dried blood spots from infants with CF [174,175]. Possible benefits from screening were deemed to be (i) a favourable alteration in the natural history of the disorder; (ii) availability of genetic counselling to avoid the birth of a second child with CF in a family where the first child remained undiagnosed; (iii) eliminating the period of prediagnosis; and (iv) the prospect of being able to conduct critical studies of new treatments. Disadvantages were thought to include adverse effects on developing family relationships with the new baby, the trauma of false-positive tests and the stigmatization of children who might only have mild disease [176–178].

### Immunoreactive trypsin

Early data that IRT is elevated in CF neonates suggested that the finding was almost always true, irrespective of pancreatic status [179,180]. However, a review of more extensive studies shows relatively high false-positive (up to 1% on the first sample) and significant false-negative rates [181]; the false-negative rate is not dependent on pancreatic function [182]. One problem with the IRT assay is that the level falls variably with age and method of assay [183,184]. Levels are raised two to five fold in the first 4 weeks of life but a negative test after 8 weeks of age is no longer informative. The value of IRT in screening was greatly enhanced by the additional ability to use the blood spots for CF gene screening.

### IRT and DNA analyses

Bowling and colleagues [185] outlined a two-tiered approach of initial IRT assessment and then DNA mutation analysis on those samples with a defined elevated IRT. Similar IRT/DNA protocols have been adopted by most screening programmes and assessments are good [186–191]. The advantage of the combined IRT/DNA method compared with IRT alone is that the number of infants receiving a false-positive screening result is reduced dramatically.

### Is early detection beneficial?

Short-term benefit has been shown for infants with CF who are diagnosed early by neonatal screening. Any evidence of altered long-term outcome is less clear-cut. The earlier reports on the benefits of neonatal screening were flawed in study design, since the outcomes for screened infants were compared with historical controls recognized in previous years [144,192–194]. However, these suggested that screened children at 2 years had spent less time in hospital [192] or gained weight better and had fewer chest infections [194]. Studies by Dankert-Roelse and colleagues [193,195,196] are of longer duration, although again the screened and unscreened populations are not entirely comparable since more of the screened patients were followed in a CF centre. The screened children had better clinical scores and survival and less decline in lung function [195,196]. In Wisconsin also, comparator groups have not been absolutely identical, although there has been evidence of some nutritional advantage (thus far up to the age of 10 years) in the group identified by screening [197]. A better-designed study for true comparison was carried out in Wales and the West Midlands of England between 1985 and 1990, in which screening was carried out only on alternate weeks and where screened and unscreened patients were followed in the same centres and therefore received identical management strategies [198,199]. Data have been recorded annually. Analysis to 4 years of age showed only shorter hospital admission time for the screened children in their first year [199]. By assessment at 8–10 years of age there was evidence that the screened group had (modestly) better lung function and nutrition (Weller, personal communication).

### Antenatal screening

Different approaches have been used in the screening of pregnant women, such antenatal diagnosis being used in hospital and primary care settings. Stepwise screening tests the pregnant woman, and her partner is only tested if she is found to be a carrier of one of the small number of CF genes tested [200,201]. Couple screening requires

mouthwash samples from both parents but only one is tested, unless that is positive, in which case the other is also tested [202,203]. A direct comparison of the two methods [204] found that couple screening allowed carriers to avoid the transient high levels of anxiety caused by stepwise screening, which occurs after the tested woman is found to be a carrier and the result from her partner is awaited. However, couple screening was associated with more anxiety and false reassurance among most screenees, who will test negative. Stepwise screening gave carriers and their relatives informative genetic facts. Population screening has also been tested in general practice [205]. Carrier testing was offered to patients of reproductive age, with an uptake of 66%. However, the cost-effectiveness of this approach is doubtful.

In one large trial when antenatal screening was offered to 8536 couples, the participation rate was 76% [203]. However, with the expected survival times of CF subjects constantly improving and the prospects of newer therapies in the future, the take-up rate is less certain. In 1998, Lothian was the only area in the UK where antenatal screening was routinely offered; neonatal screening is the preferred option of the Cystic Fibrosis Trust and others.

## Childhood management

CF affects several organ systems. Many of the problems pertaining to individual systems apply to children and adults and are considered together. Similarly, the organization of care can be applied to both age groups, although the historical predominance of CF as a paediatric disease means that paediatric centres may be better established. The evidence has been convincing that CF children fare better if their care is coordinated from a specialist centre. Indeed the recommendation of the US Cystic Fibrosis Foundation is that all patients be evaluated at least quarterly at a regional CF centre [206]. In the UK the Cystic Fibrosis Trust, British Paediatric Association and the British Thoracic Society have jointly advocated care in specialist centres. The key factor is to provide care with an experienced team. The core team should include doctor(s), clinical nurse specialists, dietitian, physiotherapist, social worker and psychologist. The addition of a pharmacist is most useful. Access to other specialists and support teams is required and is considered with the specific complications.

## Physical examination

The physical signs depend on the severity of disease. Often there may be no abnormal signs at all. With disease progression the lungs become hyperinflated and if this occurs in infancy thoracic cage deformity appears, revealed as bowing of the sternum (pectus carinatum),

Harrison's sulci and kyphosis. Digital clubbing develops. On auscultation, end-inspiratory and expiratory crackles appear, usually in the upper zones in the first instance. There may be polyphonic wheezes. In the abdomen there may be signs of hepatomegaly, splenomegaly or faecal 'masses'.

## Other assessments

Scoring systems have been established, including clinical and radiographic evidence. Investigations at each visit include lung function, weight and height. Haematological, biochemical and microbiological assessments vary in frequency depending on the patient's condition.

## Scoring systems

Clinical scoring systems in CF became pertinent once survival started to increase. The first, the Shwachman-Kulczycki score, was developed to evaluate a therapeutic programme, determine disease severity and compare one patient with the next [207]. The score is based on history, examination and chest radiograph. Respiratory function tests are not included, since at the time of the original paper these were not universally available. A maximum of 25 points and a minimum of 1 are awarded on a 5-point scale to each of four domains (Table 30.5). The 'Shwachman score' is so entrenched in CF clinical work that it is still applied even though it has been substantially outdated by the advances in CF care and patient well-being over the past 40 years and this should have confined it to historical interest; even so, there have been attempts to update it [208–210].

Other scoring systems have been suggested but also have faults. The Cooperman system [211] is rather too simple and was not really evaluated adequately. The NIH score, reported initially by Taussig and colleagues in 1973 [212], does take into account lung function tests and disease complications that were thought to influence survival (cor pulmonale, haemoptysis, pneumothorax), is reproducible and found to be useful prognostically. Stockrider and colleagues [213] have modified the NIH score in an attempt to refine it as a research tool. They found that five components accounted for 85% of the reliable consistency of the score (general pulmonary, nutrition, disability, psychosocial, acute pulmonary changes), although these had very little correlation with each other. Thus patients with the same total score could have very different component scores. Such differences limit its use as a research tool.

## Chest radiographic scoring systems

Chest radiographic scores are included in the major

**Table 30.5** Shwachman–Kulczycki score: a clinical evaluation score of patients with cystic fibrosis. (From Shwachman & Kulczycki [207].)

Grading	Points	General activity	Physical examination	Nutrition	Radiographic findings
Excellent (86–100)	25	Full normal activity; plays ball; goes to school regularly	Normal; no cough; pulse and respirations normal; clear lungs; good posture	Maintains weight and height above 25th centile; well-formed stools almost normal; good muscle mass and tone	Clear lung fields
Good (71–85)	20	Lacks endurance and tires at the end of the day; good school attendance	Resting pulse and respirations normal; rare coughing or clearing of the throat; no clubbing; clear lungs; minimal emphysema	Weight and height about 15th to 20th centile; stools slightly abnormal; fair muscle tone and mass	Minimal accentuation of bronchovascular markings; early emphysema
Mild (56–70)	15	May rest voluntarily during the day; tires easily after exertion; fair school attendance	Occasional cough, perhaps in the morning on rising; respirations slightly elevated; mild emphysema; coarse breath sounds; rarely localized râles; early clubbing	Weight and height above 3rd centile; stools usually abnormal, large and poorly formed; very little if any abdominal distension; poor muscle tone with reduced muscle mass	Mild emphysema with patchy atelectasis and increased bronchovascular markings
Moderate (41–55)	10	Home teacher; dyspnoeic after a short walk; rests a great deal	Frequent cough, usually productive; chest retraction; moderate emphysema; may have chest deformity; râles usually present; clubbing 2 to 3+	Weight and height below 3rd centile; poorly formed bulky fatty offensive stools; flabby muscles and reduced mass; abdominal distension mild to moderate	Moderate emphysema; widespread areas of atelectasis with superimposed areas of infection; minimal bronchial ectasia
Severe (40 or below)	5	Orthopnoeic; confined to bed or chair	Severe coughing spells; tachypnoea with tachycardia and extensive pulmonary changes; may show signs of right-sided cardiac failure; clubbing 3 to 4+	Malnutrition marked; large protuberant abdomen; rectal prolapse; large, foul, frequent, fatty movements	Extensive changes with pulmonary obstructive phenomena and infective lobular atelectasis and bronchiectasis

clinical scoring systems, although several independent radiographic scores have been developed since and have been used widely in staging disease severity. The most widely quoted was published by Chrispin and Norman in 1974 [214], which was usefully modified, standardized and validated by Brasfield and colleagues [209,215]. Independent assessments of the Shwachman, Chrispin–Norman and Brasfield scores reveal similar interobserver and intraobserver variations [216,217]. However, the rather simpler to apply Northern Score has the advantage of rapid and reproducible scoring by a single observer [218] (Table 30.6).

## Pathophysiology of respiratory disease

The pulmonary disease, by far the principal cause of morbidity and mortality, is suppurative and progressive. Chronic endobronchial infection leads to bronchiectasis and eventually to respiratory failure. The abnormalities of CFTR function result in relative dehydration in the pericellular layer above the epithelial cells. This appears to facilitate bacterial adherence and inhibit mucociliary clearance. This progresses to chronic bacterial colonization with intermittent acute inflammatory responses, and a vicious cycle of further airway damage, further reduc-

**Table 30.6** Northern score: a radiographic scoring system for cystic fibrosis.

Scale	Radiological changes
0	Normal: no cystic fibrosis lung disease evident
1	Mild: minimal increase in linear marking and/or nodular cystic lesions up to 0.5 cm diameter
2	Moderate: more pronounced linear marking and/or more widespread nodular cystic lesions
3	Severe: prominent increase in linear markings, profuse nodular cystic lesions, large areas of collapse/consolidation
4	Very severe: little or no area of normal lung seen, dense infiltration

Notes: The lungs are divided into four quadrants by a line drawn outwards from each hilum and each quadrant scored on a 0–4 scale based on increasing severity of chest radiographic changes. A further 0–4 points are allocated according to the observer's perception of overall severity.

tion in mucociliary clearance and further bacterial colonization. While this rather superficial explanation for a progressive, suppurative airways disease may summarize events, it does not really address the underlying mechanisms and CF generally behaves more aggressively than other forms of bronchiectasis. Some genotypes of CF display a much milder form of airways disease. These facts suggest that there are specific biochemical events in CF that determine the inflammatory and infective responses.

Mucins are important for the viscoelastic properties of respiratory mucus. These large glycoproteins, consisting of a protein core that is extensively glycosylated, are in a highly condensed state inside secretory granules of respiratory epithelial cells. During secretion into the airway lumen they undergo rapid rehydration, with a several hundred-fold expansion in volume [219]. The pericellular relative dehydration in CF may affect this process. In addition, the mucins in CF are biochemically abnormal by being oversulphated [220,221], which may result from a defect in acidification of intracellular organelles in CF cells [38] that favours the activity of sulphotransferases over other processing enzymes in the Golgi.

### Bacterial colonization

There appear to be no defects in traditional airway defences in CF. Clearly, however, bacterial colonization does take place and infective exacerbations ensue. Recent data suggest that subtle alterations in the sodium and chloride concentrations of the airway microenvironment may limit bacterial killing [222]. Further, reactive nitrogen species may be important microbicidal agents [223,224] and there is some evidence that inducible nitric oxide syn-

**Fig. 30.8** Diagrammatic representation of *Pseudomonas aeruginosa* having undergone mucoid change and residing as microcolonies within an alginate gel. The alginate provides protection from phagocyte proteinases and oxidants and inhibits antibiotic penetrance. The bronchial epithelium is subject to damage from host defence mechanisms as well as pseudomonal toxins.

thase in the airway epithelium fails to upregulate [225], which could result in relative local deficiency of nitric oxide and its reactive product peroxynitrate. Also, there is new insight into CFTR function and mechanisms relating to bacterial colonization. CFTR functions as a receptor for the binding, endocytosis and clearance of *Pseudomonas aeruginosa* in the normal lung [226], and *in vitro* gene transfer of normal CFTR to CF epithelial cells reduces the binding of *Ps. aeruginosa* to the cells [227]. There is also evidence that the same organism binds to asialo-GM1, which appears to be expressed specifically by regenerating respiratory epithelial cells [228].

Bacterial adaptation can favour persistence even in the face of an active host response. After colonization, *Ps. aeruginosa* tends to undergo mucoid change. Mucoid strains appear among organisms grown *in vitro* under sub-optimal conditions [229], and in CF airways *in vivo* the bacteria appear to be subject to similar nutritional limitations [230,231]. The mucoid change is due to marked production of alginate, which in the presence of calcium forms a firm gel. Microcolonies of organisms then exist in the alginate gel [232], protected from phagocytosis by host defence cells [233] and from antibiotics [234] (Fig. 30.8). The mucoid strains of *Ps. aeruginosa* express a different form of lipopolysaccharide [235] that makes the organism more sensitive to complement-mediated killing [236] and thus limits its ability to cause systemic infection. Indeed, despite the number of endobronchial bacteria, systemic sepsis is very unusual in these patients.

### Infection and inflammation: a vicious circle

Bacterial colonization occurs early in CF patients and is

found even in those who apparently have clinically mild disease [237,238]. The supposition has been that the presence of bacteria stimulates and maintains a host inflammatory response that is unable to eradicate the organisms and therefore persists as a 'chronic' acute inflammatory response. Whilst this is undoubtedly of major importance, bronchoscopies in very young children have revealed the presence of an acute inflammatory response driven by interleukin (IL)-8 in the absence of bacteria [239]. In addition, laboratory-based tests have suggested an intrinsic deficiency of CF epithelial cells and cloned T cells to release IL-10 [240,241]. CF may therefore exhibit an 'intrinsic' alteration of IL-8 and IL-10 responses that would favour the persistence of inflammation.

The persistence of bacteria in the airways generates a continuous antigenic load. Coupled with an exuberant antibody response, this facilitates immune complex formation and amplification of tissue damage [242]. However, most tissue damage is mediated by neutrophils, predominantly via proteolytic mechanisms and oxidants. Neutrophil proteinases are present in substantial excess compared with their inhibitors [243], with elastase occupying a position of importance. Neutrophil elastase not only causes tissue damage but also has proinflammatory activity, activating chemotactic complement components and inducing IL-8 release from bronchial epithelial cells [244]. This aids the establishment of the 'vicious circle' of inflammation, bacterial colonization and progressive bronchiectasis.

## Microbiology

A surprising feature of pulmonary infection in CF is the limited spectrum of pathogens involved, although this is increasing as patients are living longer, presumably related to the more aggressive use of antibiotics helping to 'select' organisms. Another surprising feature is that the organisms involved, which frequently are uncommon respiratory pathogens, do not cause the devastating *acute* illness that they may in other patients.

### *Staphylococcus aureus*

In the earliest microbiological study of postmortem cultures of lung tissue from CF infants, *Staph. aureus* was the predominant organism [245]. Subsequently *Staph. aureus* and *Haemophilus influenzae* were recognized as important CF pathogens, often with repeated exacerbations [246–248]. *Staph. aureus* may cause severe infective exacerbations, although the potential for therapy is greater at present than in earlier times. However, there is an emerging problem with methicillin-resistant *Staph. aureus* (MRSA). This organism does not cause more serious infections but its presence is a major problem for patients with advanced disease, since some transplant centres do not

accept such patients on to their programmes. In some clinics the frequency of patient colonization with MRSA is greater than 10% and a number are employing segregation policies, as with *Burkholderia cepacia* (see below).

### *Pseudomonas aeruginosa*

*Ps. aeruginosa* is generally regarded as the major CF pathogen but usually occurs after repeated infections with other pathogens. The incidence increases with age [249], with about 80% of patients over 26 years in the USA colonized [121], although the same survey showed an incidence of 21% under the age of 1 year. The emergence of colonization by *Ps. aeruginosa* is regarded seriously since it is often associated with an increased rate of decline in lung function. Certainly the organism has a wide range of virulence factors, including pyocyanin, elastase, exotoxin A and exoenzyme S [250–252]. Current practice is to attempt eradication procedures immediately on recognition of colonization. Different approaches include initial oral ciprofloxacin, with or without intravenous antibiotic therapy, followed by a more protracted period of nebulized antibiotics and/or intermittent ciprofloxacin [253].

An alternative, but as yet unproven, strategy to counter chronic pseudomonal infection is immunotherapy. Early attempts at using a *Pseudomonas* vaccine had proved very disappointing. A more recent polyvalent vaccine appears safe [254], and non-colonized patients who maintained high levels of antibodies in response to the vaccine have had a lower rate of infection than non-immunized patients or immunized patients who did not maintain a high-affinity response [255].

### *Stenotrophomonas (Xanthomonas) maltophilia*

Other Gram-negative organisms, such as *E. coli* and *Klebsiella* spp., cause occasional colonization. Yet others are being seen with increasing frequency and may have serious implications for the patient. *Stenotrophomonas maltophilia* [256,257] colonization may follow *Ps. aeruginosa* infections or even occur as the first major Gram-negative problem after *Staph. aureus* and *H. influenzae* colonization. This organism usually displays multiple antibiotic resistances but its effect on the longitudinal health of the patient has to be established.

### *Burkholderia cepacia*

*B. cepacia* has had a major impact in CF clinics. This organism, first identified as causing onion rot [258], was seen from the early 1970s [259] as an occasional colonizer of patients, although the frequency may have been underestimated because of inadequate laboratory culture techniques. During the 1980s and the early 1990s, the

frequency of patient colonization [260–263] increased substantially and it was recognized that certain strains were being transmitted from patient to patient [262–272]. The problems with this organism are its innate resistance to very many antibiotics and the poorer clinical outcomes for many (but not all) patients colonized [273]. A number of patients succumb rapidly to ‘cepacia syndrome’, where severe worsening of pulmonary infection is associated with septicaemia [261,274,275]. These very serious considerations, linked with the transmissibility, have led to segregation policies between colonized and non-colonized patients and bans on summer camps and similar social events for CF patients. The psychological, social and financial implications of these infection control measures have been considerable. Recent work has identified a novel genomic marker that may help differentiate transmissible and non-transmissible lineages [276]. If so, it may prove helpful in the segregation of patients.

### Opportunistic mycobacteria

The frequency of isolation of mycobacteria in the sputum of CF patients probably depends on the diligence with which these organisms are sought. Regular sputum testing and rigorous culture techniques to avoid ‘contamination’ by the organisms discussed above [277] appear to yield isolation rates of 10–20% of patients, with higher or lower rates in some clinics [278–283]. However, the true prevalence and effects of these mycobacteria are poorly understood. *Mycobacterium chelonae* and *M. avium* complex are the organisms reported most frequently to cause true infection (rather than colonization) and the criteria for ‘infection’ are not firm. Anecdotally, it has been difficult to be convinced of overt clinical deterioration in all but one of the Edinburgh Adult Clinic patients (frequency >10%), despite lack of treatment. In some the sputum becomes negative quite quickly and in others the organism persists or rarely the species changes. The one exception has been a patient colonized by *M. fortuitum*, an organism not usually viewed as pathogenic, and a fatality with this has been reported [284]. Occasional cases of *M. tuberculosis* are seen and it is important to maintain regular sputum vigilance, since the presence of such infection may be difficult to recognize clinically or radiologically, particularly in patients with more advanced disease.

### Aspergillus

*Aspergillus* spp. are recovered quite frequently from the sputum of CF patients. The clinical relevance of this is unclear. The presence of a positive sputum culture, high IgE levels, a positive skin-prick test and precipitins are sometimes taken as evidence of allergic bronchopulmonary aspergillosis. In conjunction with new radiological shadowing and a clinical response to steroids, this

may indeed be the case. Allergic bronchopulmonary aspergillosis in CF patients has been reported [285]. One report suggests that the presence of *Aspergillus* spp. in the sputum does not contribute independently to a more rapid deterioration in pulmonary status [286]. At present the best advice is that if a patient is suspected of having clinically relevant lung disease associated with *Aspergillus* spp., treatment with steroids and itraconazole should be considered.

### Viral infections

The precise role of viral infections in initiating respiratory problems or, in particular, promoting lower respiratory exacerbations is uncertain. The balance of data implies that infections with influenza A and B, rhinovirus, adenovirus and respiratory syncytial virus may be important [287–291] and affect mucociliary clearance. It is standard practice to immunize against influenza in the autumn.

## Respiratory complications

### Nasal polyps and sinus disease

The upper respiratory tract holds significant problems for the CF patient. The incidence of nasal polyposis is reported to vary from 10 to 32% [153,292–294]. There are differences between CF and non-CF nasal polyps, including the presence of acidic sulphated mucins in the CF patients [295], fewer eosinophils [296] and more mast cells and lymphocytes. The mast cells may show evidence of degranulation [297]. Approximately 50% of the CF patients appear to be atopic [292], although the relevance of this is uncertain [153,298]. Up to 40% of adults develop polyps [299]. The polyps may be multiple and large enough to cause visible nasal deformity. The presence of nasal polyps bears no relation to the severity of the lung disease.

The sinuses are affected in more than 90% of patients [292,300], involving predominantly the maxillary and ethmoid sinuses. The radiograph may show anything from mucosal thickening to complete opacification. While many patients are asymptomatic, others experience recurrent problems and the sinuses are colonized with the organisms found in the lower respiratory tract. Surgery and parenteral antibiotics may be required.

### Progressive pulmonary pathology

The initial infections favour the development of bronchitis and bronchiolitis. Repeated infection causes ulcerative bronchitis leading to dilatation of the bronchial wall with resultant bronchiectasis. This affects the proximal airways and is usually most marked in the upper zones. The process favours progressive bacterial colonization and

damage to the airways as outlined above. Bronchioles become filled with pus and there is consolidation of the surrounding lung parenchyma. Pneumonia can be seen at all stages of the evolution of the disease. Cysts occur in the lungs, particularly the upper lobes. The progressive lung damage results in deteriorating lung function, the development of pulmonary hypertension and respiratory failure.

### **Atelectasis and collapse**

Segmental atelectasis and even lobar collapse can occur. These are usually associated with thick, retained secretions, often as a consequence of an infective exacerbation. While physiotherapy and antibiotics (see below) would be standard treatment, the importance of re-expanding the lung has led some physicians to have a low threshold for bronchoscopy with suction and even lavage of the involved segment. In the patient with more advanced disease, lavage has greater potential for causing problems and may even promote a worsening inflammatory response.

### **Haemoptysis**

Small haemoptyses are common in CF, particularly in the patient with advanced disease. They are more frequent in the presence of an infective exacerbation and antibiotic treatment may be the appropriate course of action. However, isolated haemoptyses can occur in the stable patient and may simply require reassurance. Massive haemoptysis (>250 mL) is much less common but very disturbing for patient and clinician alike. It almost certainly reflects bronchial artery bleeding. In severe or persistent cases, interventional radiology with bronchial artery embolization may be a necessity [301–303].

### **Pneumothorax**

Spontaneous pneumothorax (Fig. 30.9) is not very common in childhood but the risk increases in adolescence and adulthood. It is commoner in males, in whom an incidence of just under 20% has been reported [304]. Pneumothorax may be associated with a poor prognosis [305] and in our unit has been an event leading ultimately to the death of two patients. While small, asymptomatic pneumothoraces can be treated conservatively, larger pneumothoraces require aspiration or, more commonly, intercostal tube drainage. Lack of resolution results in surgical intervention. The more limited the procedure, the better. A limited abrasion surgical pleurodesis is the preferred option. More extensive pleurodesis or talc or kaolin slurry pleurodesis are less desirable because of increased risk of bleeding at any future transplant. Pleurectomy should be avoided for this reason. The problems associ-

ated with surgical interventions have encouraged us to pursue conservative intercostal tube drainage for significantly longer periods than would be the case for non-CF patients.

### **Pregnancy**

The respiratory complications of pregnancy are considered in the section on fertility (see p. 863).

### **Respiratory failure**

In the later stages of illness patients develop hypoxic respiratory failure, leading to pulmonary hypertension and cor pulmonale. There is usually a progressive rise in carbon dioxide, and early morning headaches are common. Oxygen therapy and nocturnal ventilatory support are valuable aids to symptom control and are described below. These strategies should not be used simply to prolong survival, unless lung transplantation is actively awaited.

### **Management: lung transplantation**

(see Chapter 59)

Respiratory failure, lung infection and other pulmonary complications account for about 95% of CF deaths. Lung transplantation is the therapeutic option to prolong survival and return physical function and quality of life to satisfactory levels. The shortage of organ donors and the consequent wait for transplantation usually result in the referral for transplant assessment being made when the physician estimates a probable life expectancy of about 2 years. The first successful heart–lung transplant for CF was in 1983 (1985 in Europe) [306,307]. Single lung transplantation is not feasible in CF because of the chronic infection in the native lung, which could lead to fatal infections under immunosuppression. Heart–lung transplantation thus remained the treatment of choice [308] until the successful introduction of bilateral lung transplantation [309–311]. With this technique cardiopulmonary bypass can often be avoided, making it the procedure of choice. To date nearly 400 CF patients in the USA and more than 300 in Canada and Europe have undergone heart–lung or lung transplantation. In 1990 the first living-donor lobar lung transplantation took place and over 50 have now been performed. For patients with marked liver disease in addition to lung disease, heart, lung and liver transplantation may be undertaken, although numbers of such operations are few.

### **Referral and waiting**

In general it is helpful if the referring and transplant centres have a close working relationship. This aids patients in their anticipation of what to expect at assess-

(a)

**Fig. 30.9** (a) Chest film of a male patient with advanced cystic fibrosis. There are extensive bronchiectatic changes with a complicating pneumothorax on the left side. The film also shows a totally implanted venous access device in the upper left anterior chest wall accessed by a 'gripper' needle and standard connector for administration of intravenous antibiotics. (b) Chest film of a female patient with advanced cystic fibrosis. There are extensive bronchiectatic changes with a complicating pneumothorax on the left side. The film also shows a totally implanted venous access device in the right mid-axillary chest wall. The device is not being used so there is no external access needle. The tubing connecting the reservoir chamber and the central veins can be seen. It runs in the subcutaneous tissues upwards across the lateral and anterior chest wall to enter the subclavian vein above the clavicle and downwards within the veins to the superior vena cava.

(b)

ment, and may limit inappropriate referral of individuals. The whole process is very stressful for patients. Most do not believe they are unwell enough for transplantation when the subject is first broached, although once they have accepted the idea the time spent waiting for assessment and placement on the programme seems far too long to them. Once on a programme the usual wait for suitable donor lungs averages well over a year and a substantial proportion of patients die on the waiting list. Many receive 'false alarms', and may even be at the transplant centre awaiting the donor organs only to find them too

damaged for transplantation on arrival. These stresses mean that the support of family and CF unit carers may be invaluable.

### Preparations

CF patients require particular attention in the waiting period. Their general health is, by definition, poor and frequent infective exacerbations are to be anticipated. Indeed many become so unwell that they receive intravenous antibiotics more often than not and undergo multiple

hospital admissions. Nutrition is difficult, since most have no appetite and may become extremely breathless during eating. Nasogastric or gastrostomy tube feeding is usually essential. Supplemental oxygen therapy at night, or usually night and day, is necessary for most patients, and some benefit from nocturnal ventilatory support using BiPAP. Attention should also be paid to the bones, since a significant number of CF patients have reduced bone mineral density or overt osteoporosis. This is probably the result of low vitamin D levels through some or all of childhood combined with low exercise levels because of their respiratory disabilities. The high doses of steroid used in the immediate post-transplant period put the patients at risk of fractures. Assessment of bone mineral density before or at time of transplant referral, followed by therapeutic intervention as necessary, is important. Our policy is to use calcitriol rather than bisphosphonates, but there are no comparative studies.

### Early complications

Early mortality (within 30 days) was as low as 12% even in the earlier days of transplantation and has improved since. The 1-year survival in two large series of heart–lung transplants has been about 70% [307,308], and there are similar figures for bilateral lung transplants [312,313]. Rejection episodes are the most common early complication, with almost all patients experiencing an episode within the first month. Infection is also quite common and it is difficult to distinguish between rejection and infection on clinical grounds; fever, cough, breathlessness and chest radiographic infiltrates are typical of both. In acute rejection radiographic abnormalities are less common after 1 month [314]. Cytomegalovirus (CMV) infections, especially pneumonitis, are common in lung transplantation; ideally, CMV-negative recipients should receive organs from CMV-negative donors. Ganciclovir provides important therapy for such problems. *Pneumocystis carinii* infection is common in patients not receiving prophylactic treatment [315]. The most convenient prophylaxis is with co-trimoxazole on Fridays to Sundays.

### Late results and complications

Survival rates are improving. At present the 3-year survival is in the order of 56%, in contrast to 46% for transplants prior to 1992, and the 5-year survival is 48%. Survival rates are higher at centres that perform more transplants. There do not appear to be significant differences in survival attributable to differences in gender, age group or blood group.

Obliterative bronchiolitis is the most serious late pulmonary complication. Its development appears linked to repeated (perhaps unrecognized) episodes of rejection. Close assessment and treatment of rejection should limit

the frequency of this complication. On the other hand, immunosuppression may allow the development of lymphoproliferative disorders caused by Epstein–Barr virus. The recognition of this requires modulation of the immunosuppressive regimen and treatment with ganciclovir. A careful watch for bacterial infections is required since CF patients have bacterial colonization of their sinuses, a ready source of *Pseudomonas* and other organisms for infection of the lower respiratory tract. The non-CF phenotype of the transplanted lungs seems to help limit permanent colonization in the lower airways.

The immunosuppressive drugs have their own problems. The steroids affect glucose handling, and thus patients already on insulin need their doses modified and other patients not previously on insulin may have to start therapy. In many patients cyclosporin causes hypertension that necessitates treatment. In the long term, cyclosporin-induced renal impairment is important and there should be careful monitoring. Some patients develop a chronic anaemia unrelated to renal impairment that presumably is drug-induced. Azathioprine may be the principal culprit, although the cause is not clear-cut.

Despite the unwanted effects of the immunosuppression, particularly the high doses of steroids in the early days, patients soon observe a dramatic improvement in exercise capacity and loss of the severe problems of chronic sputum production. Despite the very marked improvement in exercise abilities the maximum tolerable exercise capacity in transplanted patients is significantly diminished compared with healthy control subjects. Heart–lung and bilateral lung transplant patients achieve a mean maximum oxygen uptake of 50–60% predicted [316–318].

## Gastrointestinal complications

### Pancreatic insufficiency

Pancreatic disease was recognized before the respiratory component of CF (see above). Pancreatic function declines during the first year of life; 92% of infants diagnosed by neonatal screening were found to have steatorrhoea by age 1 year [319], while 20% of patients found to be pancreatic sufficient at birth became insufficient within 2–12 months of evaluation [320]. Various tests have been used to test pancreatic status (see above). Clinical steatorrhoea is a florid expression of pancreatic insufficiency, occurring only after patients lose greater than 97% of pancreatic lipase and colipase secretory activity [321].

Exocrine pancreatic dysfunction is treated by giving oral pancreatic enzyme supplements. These are extracts of pig pancreas. Initially, powdered extracts were used but these were inactivated by gastric acid and pepsin. In the 1970s, enteric-coated microspheres were developed, the coating not dissolving unless the pH is greater than 5.5,

enabling the enclosed enzymes to escape the acid-pepsin gastric environment. Although pancreatic-insufficient patients have impaired secretion of all pancreatic enzymes, fat malabsorption presents the greatest difficulty. It leads to malodorous bulky stools and flatulence and, because of the calorie content of fat, weight loss. Pancreatic supplements are therefore ranked according to lipase content. The dose of enzyme supplements should be adjusted to the estimated fat content of a meal or snack. In reality most patients are poor at such estimations, and the number of enzyme capsules they use for the average meal is usually achieved by judging the clinical response. If a good clinical response is difficult to obtain or there remains doubt about the patient's level of absorption, a faecal fat balance is the most useful study to optimize enzyme dose [322,323].

With pancreatic insufficiency, the high-volume bicarbonate-rich fluid is not secreted and intraduodenal pH may remain low, since gastric acid is inadequately buffered [324]. When duodenal pH is less than 4, pancreatic lipase is irreversibly inactivated and most bile acids precipitate thus preventing micelle formation; this combination contributes to fat malabsorption.  $H_2$  antagonists and proton pump inhibitors can reduce gastric acid output and enhance the alkalinity of the duodenum [325–327]. This can be a useful adjunct for patients requiring large numbers or increasing doses of pancreatic enzymes in order to control malabsorption.

### **Fibrosing colonopathy**

In 1994 a 'new entity' for CF, fibrosing colonopathy, was reported [328]. This first report highlighted a possible association between colonic strictures and patients' intake of high-strength pancreatic enzyme preparations. It led to a UK survey, which identified 14 cases whose lipase intake was substantially higher than that of controls (46200 units/kg daily vs. 21500 units/kg daily) [329]. Similar cases have been identified in other countries. Although not all such cases had used high-strength enzyme preparations, the more recent USA case-control study has confirmed the association with high intake of enzyme supplements [330]; 29 patients had a mean lipase intake of 50046 units/kg daily compared with 18985 units/kg daily for the 105 controls. This provided a relative risk of 10.9 for patients taking 24000–50000 units/kg daily compared to those taking 0–24000 units/kg daily. In the UK the Committee on Safety of Medicines has recommended a maximum lipase intake of 10000 units/kg daily, even for adults among whom no cases have been described.

The pathology associated with the colonic strictures is that of extensive submucosal fibrosis. Some cases show evidence of mucosal injury and repair, while others show a normal mucosa. Mild infiltration with inflammatory

cells is occasionally seen, and in some there is an eosinophilic infiltrate. The condition comes to clinical attention when the colonic lumen is narrowed to the point where it causes obstruction. At operation the colon wall is thickened and firm. One report has suggested that increased thickness of the colonic wall can be detected by ultrasound [331]. This has not been confirmed by other investigators and barium enema appears a more informative investigation. However, radiological appearances of a featureless and stiffened colon were reported more than 20 years ago as features of CF [145]. This was long before high-dose or even standard-strength enteric-coated microspheres were introduced. It may be unsafe therefore to assume that radiological or ultrasound evidence of a thickened colon is sufficient in itself to suggest early fibrosing colonopathy.

### **Pancreatitis**

Pancreatitis occurs in pancreatic-sufficient patients. Pancreatic-insufficient patients usually have fatty replacement of the pancreas and too little tissue to become inflamed. Pancreatitis is seen in less than 0.5% of CF children but with greater frequency in adults (1.6–2.4% over 30 years) [121]. The diagnosis is easy to miss since pancreatic-sufficient patients are thought to be 'too healthy' or 'too old' to have CF. A sweat test should be performed in any person with unexplained recurrent pancreatitis [332,333]. Perversely, recurrent pancreatitis in pancreatic-sufficient patients may ultimately lead to pancreatic insufficiency.

### **Gastro-oesophageal reflux**

Gastro-oesophageal reflux is common in CF. It appears to be commoner than in the general population, an 'anecdotal' observation supported by a comparative study finding increased frequency in CF patients compared with their siblings [334]. The cause is not clear, although there are probably contributions from the increased abdominal–thoracic pressure gradients associated with coughing and forced expiration during chest physiotherapy and from the postural drainage positions during physiotherapy. This would provide an explanation for the reported association with severer respiratory disease [335]. A significant proportion of patients require therapy with an  $H_2$  antagonist or proton pump inhibitor.

### **Distal intestinal obstruction syndrome**

Distal intestinal obstruction syndrome is an intestinal obstruction in the ileocaecal region unique to CF that occurs after the neonatal period. The true incidence is uncertain. Retrospective case reviews have reported incidences of 12–41% [336,337], with males and females

equally affected. The syndrome almost always occurs in the pancreatic-insufficient patient. Relative dehydration, dietary changes and, in particular, inadequate enzyme supplementation may contribute. Distal intestinal obstruction syndrome occurs with sludging of intestinal contents in the ileocaecal region, with the process extending distally.

Clinically, there is crampy abdominal pain and distension, usually with a palpable mass in the lower right quadrant. Partial obstruction can extend to complete obstruction, with increasing pain and distension plus vomiting. The uneducated patient and the unaware surgeon have conspired occasionally to allow inappropriate surgery and resection of bowel. Successful medical treatment is almost always possible, particularly in the early stages, with repeated oral doses of Gastrografin, a contrast medium that exerts a strong osmotic effect. The consequent movement of fluid into the bowel moves the obstructing ileal contents. Success has also been reported using bowel irrigation with balanced polyethylene-glycol solutions [338]. Contrast enemas may be therapeutic for patients with complete obstruction [339].

## Hepatobiliary complications

The primary liver abnormality of CF affects the cells of the bile ductules, with consequent reduced bile production and altered bile acid composition [340,341]. There is resultant biliary obstruction, portal tract inflammation and eventually portal tract fibrosis and focal biliary cirrhosis [342]. The quoted prevalence of cirrhosis in CF varies from as little as 2% to as much as 25% [121,343,344]. It is extremely difficult to obtain an accurate estimate of bile ductule function and associated focal damage. Plasma hepatocellular enzymes (alanine aminotransferase and aspartate aminotransferase) and biliary enzymes (alkaline phosphatase and  $\gamma$ -glutamyltransferase) are readily measured but give very poor indication of hepatobiliary status. Nevertheless, in the absence of a better measure these are generally used as the monitors of CF liver disease.

There appears to be no relationship to CF genotype, an observation confirmed by formal studies. In one, patients identified with severe liver disease had genotypes that reflected the spectrum of mutations seen in the local population [345]. In another, 29 of 111 children and young adults had severe liver disease with portal hypertension, 19 had biochemical or clinical evidence of liver disease and 63 had no evidence of liver disease. There was no correlation between hepatic disease and CF mutation [346].

Not all liver disease is as severe. In several studies over many years, fatty change has been reported to have a high incidence in CF [2,347,348]. Since CFTR is found only in the bile duct epithelium, the fatty change presumably represents a secondary effect, for example of malabsorption.

Also, there are many case reports of prolonged neonatal jaundice in CF infants. Most appear also to have had meconium ileus, although the mechanism of the jaundice is uncertain. Cholestasis may persist for months but ultimately resolves. It is not clear whether these patients are at increased risk of developing biliary fibrosis and cirrhosis later in life.

## Assessment

Since conventional liver biochemistry appears to underestimate biliary and liver disease, additional assessments should be considered as part of routine monitoring, for example at the annual review. Upper abdominal ultrasound is easy, non-invasive and may be informative. Abnormal liver architecture and splenomegaly are indicators for repeated or additional investigations. In more advanced disease Doppler may reveal reversed portal blood flow. Ultrasound does not always reveal the presence of varices, and in our unit the presence of significant splenomegaly leads to CT contrast scanning to try to identify these.

Biliary scintigraphy often shows delayed excretion in the absence of extrahepatic obstruction, presumably reflecting biliary hypomotility or bile stasis [349]. In one study using endoscopic retrograde cholangiography-pancreatography, all patients had abnormalities of the intrahepatic bile ducts [350].

## Treatment

Medical treatments are distinctly limited. The use of ursodeoxycholic acid has become widespread during the past 5 years, although the evidence for its benefits is, as yet, unclear. Ursodeoxycholic acid is a hydrophilic bile acid that tends to replace the more toxic hydrophobic bile acids [351]. Also, it is able to stimulate bicarbonate secretion directly and thus improves bile flow [352]. The early clinical studies reported improvement in liver function when patients with CF liver disease were given high-dose ursodeoxycholic acid [353–355]. There are no studies to show whether use of this drug prevents the development or progression of cirrhosis, or indeed to identify which patients should be treated.

For established cirrhosis with portal hypertension and varices, traditional treatments such as portosystemic shunting [356] and sclerotherapy [357] have been used. Currently, major operative portosystemic shunts have been superseded by TIPSS (transjugular, intrahepatic, portal systemic shunt) procedures [358]. Patients with severe liver disease are candidates for liver transplantation. A balanced assessment has to be taken with respect to the pulmonary status. Accompanying severe lung disease may indicate the need for heart–lung–liver transplantation. Alternatively, severe liver disease may have sec-

ondary effects on the lungs (e.g. intrapulmonary shunting; diaphragmatic splinting), which would reverse on liver transplantation. Medium-term survival for liver transplantation is good; the Cambridge group reports nine children all alive at 4–55 months (median 30 months) [359].

### **Extrahepatic biliary disease**

Many CF patients have small shrunken gallbladders or bile sludging [360]. Gallstones and symptomatic gallbladder disease are seen frequently, usually in adults, with CF [121,361]. It is thought that the large faecal bile acid losses and decreased bile acid pool cause the bile to become supersaturated with cholesterol, which leads to stone formation [362]. The management for most patients is laparoscopic cholecystectomy.

### **Nutritional consequences of, and implications for, cystic fibrosis**

Clinicians have long recognized that patients who are underweight have a worse prognosis than well-nourished patients, but does poor nutrition cause the decline or is it merely a marker of disease progression? Mortality patterns over a 20-year period obtained from the Canadian Patient Data Registry suggest that being underweight is, at least partly, an independent predictor of mortality [363]. Body cell mass (BCM) is the portion of metabolically active fat-free mass. Assessment of anthropometric parameters, lung function and BCM in 61 patients aged 5–17 years with moderate disease showed that change in BCM was the best predictor of change in forced vital capacity (FVC), and those patients with normal growth in BCM had less decline in FVC than those with retarded growth of BCM [364]. Generally, BCM increases with increasing calorie intake. However, the use of nutrients is controlled hormonally, particularly by insulin. In CF there may be relative insulinopenia (see below), which may contribute to reduced anabolic activity.

The association of poor nutritional status and poor lung function is presumed to be the result of increased energy expenditure from lung infection and inflammation and increased work of breathing. While these have a major effects, it has also been speculated that the CF gene defect itself may elevate energy expenditure, as a result of both abnormal ion channel kinetics and increased activity of mitochondrial electron transport.

The other aspect to consider is the dietary intake. Recommendations for daily intake are between 120 and 150% of normal recommended intake. In practical terms this is not always easy when the patients are relatively fit and well. When they are unwell, the consequent anorexia makes it even more difficult. When patients have moderate to severe disease, they have to contend with a degree of

constant anorexia. At this stage also, poor nutrition has a deleterious effect on the individual's ability to resolve infection and inflammation.

### **Dietetic support**

The dietitian has an important role in the management of CF patients by monitoring body mass index and lean body mass as well as reviewing the average daily calorie intake and pancreatic enzyme use. Dietary advice is important since it is difficult to achieve a high calorie intake without adequate use of fats, and this requires guidance with respect to pancreatic enzymes. In addition, malabsorption results in low levels of fat-soluble vitamins and it is standard practice to advise supplementation with vitamins A, D and E. When patients have difficulty keeping their body mass index in the range 19–20 or better (normal range 20–25), they should receive high energy-containing oral supplements. The newer preparations appear more palatable than some of their predecessors. In the patient with more advanced disease additional measures are often needed. Overnight enteral feeding via a nasogastric tube (passed by the patient every night) or a gastrostomy tube is a very effective way of maintaining reasonable nutrition.

### **Diabetes mellitus and cystic fibrosis**

Changes in glucose metabolism were observed in the very early descriptions of CF [2,365] and the association between CF and diabetes mellitus was first recognized in 1955 [366]. Subsequently, different studies have reported varying prevalences of impaired glucose tolerance and diabetes mellitus, although methodologies have varied [367–373].

The Copenhagen centre has provided some of the more comprehensive data. For a planned longitudinal study over 5 years all 226 patients over 2 years of age were entered; 191 patients completed the 5 years. During the study the prevalence of diabetes increased from 11 to 24%, with an average annual incidence of 3.8%. For those aged 10 years or more the respective figures were 16%, 34% and 5.0% [374]. The median age of diagnosis for diabetes was 21 years (range 3–40); 22% of oral glucose tolerance tests showed impaired glucose tolerance, although the overall picture was complex. Nearly 60% of subjects with impaired glucose tolerance showed normal glucose tolerance at their next annual test. Overall only 37% of patients had a normal test on all five occasions and impaired glucose tolerance gave a higher risk of developing diabetes (odds ratio 5.6). This study highlighted that an oral glucose tolerance test is the gold standard for assessment. Routine assessments of hyperglycaemic symptoms, fasting hyperglycaemia and glycated haemoglobin did not identify diabetes mellitus reliably.

## Pathogenesis

In patients with CF who have diabetes, there are reports of a 30–50% reduction in the number of islets and  $\beta$  cells [375–377]. With the additional observations of fibrotic bands, a shrunken fibrotic pancreas and presumptive distorted blood supply, the prevailing view has been that diabetes develops in CF as a secondary effect of progressive damage to the pancreas as a result of CF-related abnormalities in the exocrine pancreas. However, more recent data have shown that diabetes in CF appears to be type II diabetes [378,379] and that patients often have non-CF relatives with type II diabetes. This has led to the suggestion that CF is a risk factor that interacts with the genetic predisposition for type II diabetes, resulting in clinical disease.

## Management

There is some suggestion that insulin treatment of diabetic patients improves lung function and reduces infective exacerbations [380]. In our own unit we have observed evidence of improved nutrition and body mass index after introduction of insulin treatment. In addition, diabetic patients with CF are probably no less prone to developing late diabetic complications than are other patients with diabetes of similar duration and glycaemic control. An ideal approach appears to be to run a combined clinic with an interested diabetes service. However, the dietetic input is different from that in conventional diabetes management. Since CF patients have such difficult nutritional demands, their diet should be directed accordingly and insulin therapy adjusted to the dietary intake.

## Arthropathy and vasculitis in cystic fibrosis

Acute or subacute arthritis is seen in patients with CF and has been well reported [381–384]. In our own adult unit about 5% of patients have intermittent problems of arthritis, occasionally with the associated symptoms being their principal clinical concern. Usually, there is an adequate response to non-steroidal anti-inflammatory drugs (NSAIDs). However, there are reports of individuals developing persistent synovitis and progressive erosive arthritis [383], and also isolated reports of concurrent arthritis, psoriasis and CF [385] and sarcoidosis, arthropathy and CF [386]. As an additional anecdote, one of our patients with intermittent arthropathy also has biopsy-proven sarcoidosis.

Sometimes episodic arthritis is associated with erythema nodosum or other nodular skin lesions. More commonly, purpura may be seen, particularly on the legs [387–389]. In a report of 12 patients with dermal vasculitis two had evidence of systemic vasculitis [389]. There was

no evidence of autoimmune disease but 40% had antineutrophil cytoplasmic antibodies. Purpuric vasculitis is probably associated with severer lung disease. It is a matter for conjecture as to whether lung-derived immune complexes are part of the underlying mechanism. Anecdotally, some severely ill patients awaiting transplantation experience fevers and arthralgia that are suppressed by systemic steroids.

## Fertility and pregnancy in cystic fibrosis

With the marked improvements over the past 30 years in patients' well-being and survival, 'new' CF-related problems have arisen. Many now have the expectation and wish to have children. Two problems therefore have to be addressed: infertility, especially in the male, and the risks of pregnancy.

### Male fertility

Infertility is almost universal among males (approximately 2% appear fertile [390,391]) as a consequence of a developmental defect of structures derived from the embryonic wolffian duct. This leads to absence, atrophy or various forms of obstruction of the vas deferens, the body and tail of the epididymis, and the seminal vesicles [392–396]. However, testicular histology appears normal and active spermatogenesis occurs, although some abnormal and immature sperm may be seen on testicular biopsy [392,397]. As discussed above, during fetal growth CFTR function appears critical for the normal development of the wolffian duct structures, and congenital absence of the vasa deferentia may be the only manifestation of CF.

The potential for fertility can be readily assessed by checking for azoospermia. It is important to introduce the likelihood of male infertility gently, during adolescence, when the concept is less threatening. However, new techniques of sperm aspiration from the epididymis or vasa efferentia and *in vitro* fertilization [398] are now being introduced in the management of male infertility in CF.

### Female fertility

As a group, females with CF have reduced fertility compared with healthy subjects. The extent of the reduced fertility is unclear, and individual patients have normal fertility, subfertility or absolute infertility. One frequently quoted study, which gives a group estimate of about 20% normal fertility [399], appears flawed in design and details. Primary and secondary amenorrhoea are common [400], often reflecting poor lung health and nutrition [401]. These contribute to overall reduced fertility. Anatomically the female reproductive tract appears normal, although

relative dehydration of the cervical mucus may result in a physical barrier to sperm penetration [399].

In the absence of a simple screening test to assess fertility in women with CF, all patients of child-bearing age should be presumed to be potentially fertile and those wishing to avoid pregnancy for personal or health reasons should be counselled on appropriate forms of contraception. Oral contraceptives generally are effective and in limited-size studies have not shown problems [400,402], although there are potential difficulties. Chronic use of oral contraceptives has been associated with intrahepatic cholestasis and cholelithiasis; some of the progestogens used impair glucose tolerance; and oral contraceptives may deplete vitamin D and E levels. Finally, concern has been expressed over possible antagonistic effects of antibiotics on the intestinal absorption and bioavailability of oral contraceptives. If pregnancy is definitely contraindicated, a more definitive contraceptive measure should be given serious consideration.

### Pregnancy

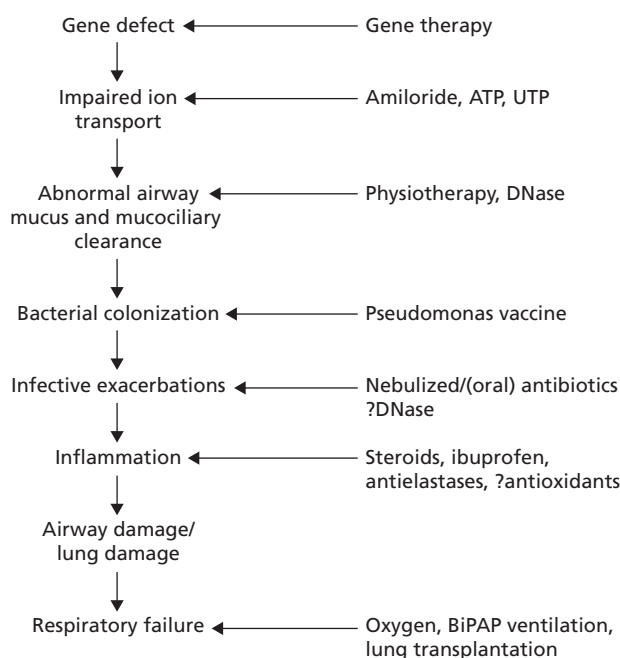

The first documented successful pregnancy in CF was in 1960 [403]. However, the patient died 6 months postpartum. The next report, in 1966, of a survey of 13 pregnancies in 10 patients from 34 CF centres revealed that five women experienced significant pulmonary decline during pregnancy and two died in the immediate postpartum period [404]. A further large survey of 119 CF centres in the USA and Canada, published in 1980, reviewed 129 pregnancies in 100 patients [405]; 75% of the pregnancies were completed, 89% of which resulted in viable infants; 12% of the women died within 6 months of delivery. The women who died were noted to have severe pulmonary disease before pregnancy. A similar association was observed in a smaller report published in 1983 [406]. Supporting this concept, a survey of 38 pregnancies in 25 women, predominantly with mild disease (half were pancreatic sufficient), indicated that pregnancy was well tolerated [407]. In contrast to the preceding studies, a recent UK report of 22 pregnancies in 20 patients recorded lung function before pregnancy, immediately after delivery and after pregnancy [408]; four mothers died up to 3.2 years following delivery. The previous observations were supported but with firmer data. The women with moderate to severe lung disease (forced expiratory volume in 1 s,  $FEV_1$ , <60% predicted) before pregnancy fared worse, producing preterm infants and suffering increased loss of lung function and mortality compared with mildly affected mothers.

Pregnancy is therefore not to be undertaken lightly. There should be very careful assessment of an individual's health and sound counselling provided. Patients whose  $FEV_1$  is less than 60% predicted should be cautioned about the risks. Pregnant mothers, even those with mild CF, should be monitored closely during pregnancy. Maternal

weight gain and uterine fundal height may help assess fetal growth retardation [409]. Antibiotic therapy should be given if needed. However, aminoglycosides and quinolones are potentially teratogenic and are best avoided, although they have been used by pregnant patients without consequences for the fetus [407]. From our own and others' observations, the immediate postpartum period may have its own hazards. We have seen severe respiratory exacerbations occur at this time. The reasons are unclear, although there must have been a release of the upward displacement of the diaphragm and associated possible closure of small basal airways. More importantly, the immunological changes of pregnancy, which are predominantly 'immunosuppressive' and anti-inflammatory, revert to 'normal'.

### Management of respiratory aspects of cystic fibrosis

There are several well-established areas of management of the various respiratory aspects of CF. These can be viewed in respect to the pathogenetic processes involved, as outlined above and as illustrated in Fig. 30.10. Also, there is much active research in CF and new and novel approaches to management are in constant development. In this section, the standard and new management techniques are reviewed.

**Fig. 30.10** A flow diagram outlining the pathogenetic sequence of events causing airways and lung disease in cystic fibrosis. The points of therapeutic interventions, both established and in development, are indicated.

### Physiotherapy

For over 40 years chest physiotherapy has been the principal technique for attempting to remove viscid secretions from the airways and thus interrupt the cycle of infection, inflammation, tissue damage and decreased clearance. First introduced in the 1950s, the combination of postural drainage, percussion, vibration, deep breathing and coughing constitutes 'conventional' chest physiotherapy and for many years has been the gold standard [410]. When introduced, virtually all patients were children and their parents could assume responsibility for performance of the treatment. As survival has improved, more and more adolescents and adults have had to assume responsibility for carrying out their own physiotherapy. Adherence to treatment is often poor among adolescents and adults. Newer techniques have been developed to try to make physiotherapy more patient-centred and to aid compliance. The active cycle breathing technique has been shown to be as effective as conventional physiotherapy in mobilizing secretions [411–413] and is less likely to cause oxygen desaturation [414]. It undoubtedly allows patients more independence. No added benefit to this technique has been provided by a positive expiratory pressure mask or a Flutter VRP1 system [415,416], although both have had their advocates. Autogenic drainage has been reported favourably with respect to both mobilizing secretions and avoidance of oxygen desaturation [417–419]. However, since adherence to treatment is such a problem it is important to select the technique that the patient prefers. There are many likely benefits of regular exercise, including improved cardiorespiratory efficiency, respiratory muscle function, muscle strength and exercise tolerance, as well as improved self-image and well-being. Exercise alone does not appear as efficient as physiotherapy in mobilizing sputum but is a valuable adjunct [413] and to be encouraged.

### Antibiotic treatment

Aggressive antibiotic therapy has probably been the major contributor to the improved survival of CF patients. Use falls principally into two categories: acute treatment for an infective exacerbation and chronic administration as maintenance therapy intended to decrease the bacterial load in the lung and to maintain lung function. Intravenous administration and nebulized antibiotics have their own intrinsic problems. In addition, pharmacokinetics are different in CF patients, who appear to have a larger volume of distribution and increased clearance of aminoglycosides and  $\beta$ -lactams, with a shorter elimination half-time and lower peak plasma antibiotic concentrations [420]. A larger dose and possibly more frequent dosing intervals are necessary to compensate for these differences. Children with CF appear to eliminate ciprofloxacin

more rapidly than older patients and may require higher dosing of fluoroquinolones [421].

### Combination therapy and aminoglycosides

Repeated courses of antibiotics lead to increased bacterial resistance patterns, and this may be an important reason for the emergence of bacterial colonization by organisms with multiple innate antibiotic resistances. Certain principles appear useful. Treatment with combinations of antibiotics appears to combine the additive benefit of two or more drugs, while in one clinic the use of monotherapy has resulted in widespread resistance to the antibiotic by *Ps. aeruginosa* [422]. Aminoglycosides in particular seem to be useful drugs to combine with other agents such as cef-tazidime, aztreonam and meropenem. The ototoxicity of aminoglycosides is an important consideration, since a patient is likely to have multiple courses. Despite rigorous monitoring of blood levels and no record of 'toxic' levels, two patients in the Edinburgh adult clinic have experienced tobramycin-related vestibular problems. Once-daily aminoglycoside dosing has been used increasingly for non-CF-related disease, but in CF there are extremely limited, almost anecdotal, reports. In the Edinburgh clinic, a 6-month period of once-daily tobramycin (5 mg/kg at night) appeared to be associated with a more rapid 'relapse' rate of exacerbation, although the treatment approach has not been assessed in a prospective double-blind fashion.

### Chronic antibiotic therapy

A number of centres treat children with regular anti-staphylococcal drugs, especially flucloxacillin, from the first isolation of *Staph. aureus*. Other centres prefer to treat infections aggressively as they occur, often maintaining treatment for 4 weeks. This has the advantage of including *H. influenzae* in the treatment spectrum. This regular flucloxacillin therapy has had an element of 'tradition' about it. Nevertheless, recent data from a study of infants diagnosed at neonatal screening showed that those who received continuous flucloxacillin had less frequent cough and fewer and shorter hospitalizations compared with infants treated with episodic courses of antibiotics. There was no difference in pulmonary function between the two groups at 1 year [423,424].

The use of regular antibiotics has been applied in older patients colonized by *Ps. aeruginosa*. In this instance, the route of administration has been by nebulizer. There have been differences in frequency of such treatment between the USA and Europe. Regular nebulized colistin is employed frequently in the UK, nebulized gentamicin or tobramycin less often. There are issues of drug-induced bronchoconstriction in patients (sometimes quite a high frequency) and adherence among adolescent and adult

patients to a twice-daily regimen is probably even less good than to physiotherapy. There are numerous published studies with nebulized antibiotics [425] but very few address long-term use and very few are placebo-controlled [426–428]. On balance, treated patients have positive benefits including better lung function and/or fewer hospital admissions. Recent, well-controlled, multicentre studies have been performed in the USA. The first, although short term, showed benefit to lung function [429]. The second, also led by Ramsey, has been in progress for a year and has shown definite benefit [430].

### Intravenous antibiotics

Recurrent infections, particularly after colonization with *Ps. aeruginosa*, require repeated courses of intravenous antibiotics. Traditionally, peripheral intravenous cannulae or long lines have been used for this purpose. However, frequent replacements are often required in a single treatment period and resulting damage to veins makes venous access difficult in the long term. The introduction of the totally implantable venous access device (TIVAD), also known as 'ports', has provided a solution to this problem. A TIVAD usually consists of a silicone septum mounted in a titanium chamber, which is inserted subcutaneously on the chest wall (see Fig. 30.9) or in the arm. The chamber is connected to a catheter, which is tunnelled into a central vein. These devices have proved successful clinically [431–435] and have greatly aided home intravenous antibiotic management. Home treatment is appreciated by patients, who avoid prolonged hospital admissions, but is dependent on adequate support. Clinical nurse specialists can provide that support and train the patients in the aseptic techniques necessary for self-administration of drugs. An important safety proviso is that the initial dose of any course of intravenous drugs is given under supervision in case of an anaphylactic response, which occasionally occurs even if the patient has received the same drugs on numerous previous occasions.

### Therapy with DNase

CF sputum is remarkably tenacious and the physical effort of expectoration, particularly in patients with poor lung function, is substantial. Much of the viscosity is attributable to DNA in the sputum, the source of which appears to be dead neutrophils. In the late 1950s, use of DNase to cleave the DNA was found to be effective at reducing sputum viscosity and aided sputum clearance. Unfortunately, marked allergic reactions occurred after a short while, since the DNase was of bovine origin, and the treatment fell into disuse. More recently, human DNase has been cloned, mass produced and was licensed for use in 1994. It is markedly effective in reducing sputum

viscoelasticity *in vitro* [436] and *in vivo* early trials showed encouraging improvements in spirometry [437,438]. The large, multicentre trial (968 patients) used to support licensing [439] showed that once-daily treatment gave a relatively modest (5.8%) improvement in FEV<sub>1</sub> at 24 weeks, with a small reduction in exacerbations requiring parenteral antibiotics. However, there was wide variability of individual responses to treatment, with a significant proportion appearing to have no benefit. Further studies have shown no significant benefit of short-term use during exacerbations [440], improvements in spirometry but not in antibiotic use in sicker patients [441], and a wide scatter of spirometric responses with a reduction in historical antibiotic use in children [442]. One longer-term study has suggested no benefit for lung function, nutrition or hospitalization rates [443]. However, group mean data may be misleading if 'non-responders' are included in the study group. Anecdotally, in our centre there appears to be a reduction in requirement for antibiotics over about a 2-year period if the drug is targeted to patients who show a definite response to short-term testing [444]. The initial persuasive reason for testing patients' responses to DNase, i.e. to target therapy, was its great expense. The cost of therapy cannot be ignored; at more than £7000 per patient per year for once-daily dosage, it equates broadly to the per capita cost of caring for CF patients in a specialist centre [445] and thus prescription to all patients would nearly double the cost of CF care in the UK. A Scottish protocol has been developed to target the use of DNase [444], and this protocol or similar should be applied before commencing patients on long-term DNase.

### Treatment of the excessive inflammatory responses

Following the recognition that host inflammatory responses are major contributors to the progressive lung damage (see above), therapeutic strategies have been directed towards control of these responses.

### Corticosteroids

An initial trial reported benefit in children aged 1–12 years when given high doses of prednisone (2 mg/kg on alternate days) [446]. The steroid-treated children were said to have had better lung function and growth, and fewer hospitalizations, with no adverse effects. This trial prompted a larger, multicentre study. Two alternate-day dosing regimens (2 mg/kg and 1 mg/kg) were compared with placebo over a 4-year period in 285 children aged 6–14 years. There were benefits to lung function but growth retardation, glucose abnormalities and cataracts occurred even at the lower dose of prednisone, and the treatment limb at the higher dose had to be discontinued early

because of unacceptable side-effects [447,448]. Although long-term steroid therapy is inappropriate because of this, there may be a place for short courses or inhaled treatment. A 12-week course of prednisolone produced improvements in lung function and serum IgG and cytokine concentrations [449]. Early results from trials of inhaled steroids are equivocal but suggest the approach is worth pursuing [450–452].

### Non-steroidal anti-inflammatory drugs

NSAIDs have anti-inflammatory effects, for example ibuprofen can inhibit neutrophil migration and release of lysosomal enzymes. In a rat model of chronic endobronchial infection with *Ps. aeruginosa*, ibuprofen decreased inflammation without increasing the lung burden of organisms, probably in part by interfering with the production of leukotriene B<sub>4</sub> [453,454]. In patients it proved possible to achieve the necessary blood levels without overt side-effects [455]. A 4-year trial of ibuprofen was then conducted in 85 patients with mild lung disease aged 5–39 years. Treated patients had less decline in lung function and chest radiographic scores, preserved body weight and tended to have fewer hospital admissions than placebo-treated patients [456]. However, the effects were most pronounced in the youngest patients (5–13 years), while the data for adults were not impressive. Given that NSAIDs may cause serious problems at times, the case for treatment of adults has yet to be made.

### Antiproteases

Elastase, predominantly from neutrophils, is found in the active state, often in high concentrations, in CF sputum. This implies that the natural inhibitors of neutrophil elastase in the airways,  $\alpha_1$ -antitrypsin, secretory leukocyte protease inhibitor (SLPi) and elafin, have been 'overwhelmed' by the total elastase burden. Elastase has proinflammatory effects as well as tissue-destructive actions. It cleaves complement components to active chemotactic products and induces release of IL-8 from epithelial cells. Antielastases should therefore exert anti-inflammatory as well as tissue-protective effects. The definitive studies have yet to be done but the principles of treatment have been addressed. A preliminary study in 12 patients showed that nebulized  $\alpha_1$ -antitrypsin twice daily for 1 week suppressed elastase activity [457]. Aerosolized recombinant SLPi 100mg twice daily to 16 patients decreased active elastase and IL-8 in the airways [458], although a lower dose failed to decrease elastase [459]. This area of management requires further study. Empirically, an antielastase delivered via the circulation appears to have greater likelihood of action at relevant sites than nebulized drug.

## Newer therapies in development and trials

### Therapies based on CFTR defects

CFTR mutations that involve premature stop codons lead to early termination of CFTR mRNA (class I mutations) (see Fig. 30.2). Some aminoglycoside antibiotics can suppress these nonsense mutations and restore full-length CFTR mRNA protein to the cell [460]. There are a number of current trials of intranasal gentamicin in patients who carry two such mutant alleles (e.g. G542X, R553X, R1162X or W1282X).

Class II trafficking mutations, such as  $\Delta F508$ , are defective with respect to structural assembly in the endoplasmic reticulum and are not efficiently glycosylated or transported to the cell surface. The  $\Delta F508$  protein retains some chloride channel function and may be more readily transported to the cell surface by treatment with 'chemical chaperones' such as glycerol. These are thought to facilitate protein folding and stabilize protein structure, thus promoting processing and trafficking to the cell surface [461]. A number of chaperones are being investigated *in vitro* in order to identify candidates for *in vivo* study. An alternative agent is phenylbutyrate, an oral analogue of butyrate, which was developed to treat urea cycle disorders. Phenylbutyrate regulates the expression of many genes, including CFTR, and promotes trafficking of the  $\Delta F508$  protein *in vitro* and *in vivo*. Encouraging phase I trials have been conducted at Johns Hopkins, Baltimore and been reported at the North American CF Meeting [462].

Class IV mutations have partial responses to cyclic AMP stimulation. A number of agents that may increase CFTR activation are being investigated. Milrinone is a phosphodiesterase inhibitor that improves chloride conductance by  $\Delta F508$  in a mouse model of CF [463]. Genistein is a tyrosine kinase inhibitor that augments chloride channel activity in CFTR via inhibition of protein phosphatase and possibly by a direct effect on CFTR itself [464,465]. The xanthine A<sub>1</sub> adenosine receptor antagonist 8-cyclophenyl-1,3-dipropylxanthine specifically activates the  $\Delta F508$  chloride channel [466] and a phase I trial is in progress. Any of these compounds, or their successors, might be used alone or in combination with other agents.

### Gene therapy

The goal in gene therapy of CF is the replacement of CFTR function at a level that will prevent the progressive damage to the airways. Ideally, this would be targeted at children before the onset of pulmonary disease. The success or failure of gene therapy depends to a great extent on how much transgene expression is needed to correct the phenotype. Some individuals who are phenotypically

normal have up to 92% abnormally spliced mRNA, which results in a defective protein [69]. This suggests that less than 10% of normal mRNA expressed in airway cells may be sufficient. However, since the majority of cells of the respiratory epithelium are terminally differentiated, vectors for CF gene therapy must be able to infect non-dividing cells. Both viral and non-viral strategies have been considered and numerous studies have demonstrated the principles of *in vivo* gene transfer in a variety of animal species.

Adenoviral vectors have been based on adenovirus serotypes 2 or 5, which exhibit tropism for the respiratory epithelium. Potential advantages of adenovirus vectors include this natural tropism for airway epithelium, the ability to transduce non-dividing cells and the capacity to be produced in high titre. Initial animal studies [467] demonstrated that adenoviral vectors could deliver transgene to all major cell types of the respiratory epithelium. However, these preclinical studies also made clear that adenovirus administration is associated with a dose-dependent inflammatory response and a (consequent) loss of transgene expression [468–470].

Adeno-associated virus vectors have also been considered for CF gene therapy. Like adenovirus, they exhibit tropism for the respiratory epithelium and are able to infect non-dividing cells. In contrast, they are naturally replication deficient and are not associated with any known human disease. However, they are small and CFTR cDNA is at the upper limit of packaging size, which places constraints on which promoter and enhancer can be incorporated. *In vivo* studies in rabbits [471] and monkeys [472] have demonstrated that safe and efficient delivery of transgene can be achieved following endobronchial administration, with expression persisting up to 6 months and no evidence of inflammation or other toxicity. On this basis phase I clinical trials have been initiated.

Cationic liposome-mediated gene delivery was first described in 1987 [473] and has been widely used to transfer DNA to a variety of cell types *in vitro* and *in vivo* [474]. Unlike adenoviral vectors, liposomes are non-immunogenic and offer advantages in terms of bulk production and quality control. Cationic liposome-mediated gene delivery to the airway was first demonstrated in mice in 1989 [475], and delivery and expression of CFTR in the airways of normal mice in 1992 [476]. Correction of the cyclic AMP-dependent chloride transport defect in CF mutant mice followed [477,478] and, subsequently, phase I clinical trials.

To date, nine clinical trials involving 78 CF patients have been published [16,479–486] and at least four others are in progress. These clinical trials have progressed from an open, uncontrolled study using the nasal epithelium of three patients to nebulized administration of the vector to the whole airways. They have clearly demonstrated that

the principle of transfer and expression of normal CFTR cDNA to airway epithelium can be achieved by both viral and non-viral approaches. However, in all of these trials there was low efficiency of gene transfer and no ideal method of judging the adequacy of correction of the physiological defect. Furthermore the expression of transgene was transient, lasting less than 2 weeks in most cases, confirming the need for repeated administration. Studies with current adenoviral vectors suggest that the presence of neutralizing antibodies raised against an initial administration severely limits the efficiency of subsequent doses. Clearly, improvements in delivery and persistence of expression are required for any realistic prospect of therapeutic benefit. Attempts have been made to reduce the immune response by modifications of the adenoviral genome, which reduces expression of adenovirus proteins [487], or by interfering with MHC class I expression on the cell surface of infected cells, thus suppressing viral antigen presentation [488,489]. For non-viral delivery systems the most important issue is to improve the efficiency of transfection. Cationic liposome-based gene therapy has the further drawback of being non-specific. Attempts have been made to circumvent this problem by incorporating ligands for cell surface molecules into the DNA–liposome complexes. However, despite initial successes *in vitro* [474], this approach has yet to be proved *in vivo*. Effort has gone into the development of novel cationic liposome formulations and to optimizing formulations of currently available liposomes by mixing with neutral colipids [490]. Some of these novel cationic liposomes appear more inflammatory than the original formulations, raising concerns for clinical safety. The first reports of a phase I clinical trial involving application of the cationic lipid GL67 to the lung supports such concerns.

Thus, after 5 years of clinical gene therapy trials (and only 9 years after identification of the CF gene), trial results hold promise of effective therapy but, realistically, the delivery of that promise appears a further decade away.

### **Holistic care for adults and adolescents with cystic fibrosis**

The idea that the management of CF can be neatly packaged into therapeutic areas (exciting and new though they are) avoids the realities of care. Patients' problems are psychosocial as well as physical and require holistic care provided by a team of experienced people. Adolescents with CF have all the problems of healthy adolescents but compounded by physical limitations and additional requirements. The extra nutritional needs and the time for self-treatment (physiotherapy, nebulized therapies) test patient adherence to the limits. Educational pressures, limitations on close contact with friends with CF (*B. cepacia*

transmission), parental difficulties in 'letting go', and the move from paediatric to adult clinic care all severely test patients' emotional strengths. Transition clinics, with adult clinic team members meeting the patients in their familiar paediatric clinic surroundings, and contact with patients and families in their home surroundings may smooth the passage of patients into adult clinics. Adults too have many psychosocial problems that have to be addressed. These include independent living, establishment of permanent relationships and further education and employment, usually in the face of declining physical health. Generally, carers in CF centres are experienced in the support of patients with regard to employment and education [491].

It remains a little unclear how the health problems of CF

patients influence their quality of life. Often psychological studies find similar quality-of-life scores to people with minor health problems and even healthy controls [492–494]. However, this may reflect the limitations of the tools used to measure quality of life and patients' reduced expectations. Certainly their health perceptions impact on their therapies. One study has suggested that patients who cope well with their disease may be less adherent to their various management regimens than those who worry about their disease and who perceive that they have little personal control over it [495].

All these issues emphasize the need for 'art' as well as 'science' in providing care for CF and the need to be involved in the 'whole' patient contributes to the rewarding nature of CF management.

# PULMONARY FIBROSIS

ANTHONY SEATON

Pulmonary fibrosis is the end-result of a multiplicity of pathological processes, from infections to autoimmune diseases. Many of these are of unknown aetiology but have characteristic features that allow them to be classified as distinct disease entities. Among them is one that typically occurs in older males, is slowly progressive, poorly responsive to therapy and has well-defined clinical, radiological, pathological and functional characteristics, known as idiopathic pulmonary fibrosis or cryptogenic fibrosing alveolitis. The latter term, coined by Scadding [1], is probably to be preferred as it emphasizes the inflammatory reaction in the alveoli that precedes the fibrosis. The danger implicit in either term is that all patients with pulmonary fibrosis are labelled 'of unknown aetiology' and the doctor forgets that all diseases must have a cause that is worth seeking. As with cardiac failure, the term 'pulmonary fibrosis' describes a clinical end-point of many different pathological processes, and the adjective 'idiopathic' or 'cryptogenic' should only be applied after appropriate thought.

In fact, the first description of the idiopathic condition concerned a rather atypical and acutely progressive variant, which still sometimes goes by the names of the original authors, the Hamman-Rich syndrome. They described five patients with progressive dyspnoea, following a fulminant course and leading to death with cor pulmonale or respiratory failure within 6 months [2,3]. It subsequently became apparent that this form of the disease was uncommon and that the majority of patients pursue a more chronic course lasting for several years [4-6].

Cryptogenic fibrosing alveolitis is a progressive fibrosing inflammatory disease of the lung of unknown aetiology. Most patients present with dyspnoea, although some are detected at an asymptomatic stage by the coincidental finding of clubbing, crepitations or radiological changes. Bilateral pulmonary crepitations are almost always audible and finger clubbing is often present. In the author's experience, very marked clubbing denotes a more chronic process. Lung function testing shows a

restrictive defect with diminished gas transfer, and inflammation and fibrosis are evident distal to the terminal bronchioles on lung biopsy. Similar clinical, radiological and pathological findings may occur in pulmonary fibrosis associated with connective tissue diseases (see Chapter 53), asbestosis (see Chapter 54) and certain drugs (see Chapter 55).

## Aetiology

By definition, cryptogenic fibrosing alveolitis is of unknown aetiology. However, this should not close the clinician's mind, since the disease must have some cause or causes, be they genetic or environmental. As with most diseases it is likely that there will eventually prove to be several contributing environmental causes operating in someone who is genetically susceptible. There are now some clues relevant to both factors.

The evidence for a genetic cause is not strong, most cases occurring quite sporadically. However, many familial cases have been described [7-11], including the finding of subclinical disease in relatives of patients [12]. Occasionally the occurrence of the condition in monozygotic twins separated from birth has suggested a genetic influence [10,13]. When the condition occurs in families it is probably transmitted as an autosomal dominant with incomplete penetrance. No consistent association with human leucocyte antigen (HLA)-A or HLA-B foci has been found [14-16], although one study has recorded an increased frequency of the B-cell alloantigen HLA-DR2 in patients (65%) compared with controls (26%) [17]. Studies of gene loci in patients with familial disease have also been confusing, in some subjects pointing to loci on chromosome 14 and in others to chromosome 6 [11,18]. Evidence from animal studies and from studies of human responses to fibrogenic stimuli due to drugs suggests that individuals differ on a genetic basis in their lung fibrogenic responses, although it is likely that these differences are mediated by complex mechanisms that probably differ from person to person. They presumably involve the

genotypic control of HLA type or of any one or more of the large number of cytokines and receptors involved in the processes between the environmental stimulus and the deposition of collagen [19,20].

The more likely primary causes in most cases are environmental. This is supported by the considerable similarities between the cryptogenic disease and pulmonary fibrosis caused by asbestos and cytotoxic drugs, by the increasing evidence that the condition is becoming more prevalent and by the differences in trends in different countries, evidence not wholly explained by changes in diagnostic preferences [21–23]. It has been suggested that there is an association with infection by Epstein–Barr virus, although studies of viral genes have shown markedly different frequencies [24,25]. Nevertheless, patients not infrequently give a history suggestive of viral infection prior to the development of the disease [26]. Diffuse fibrosis has also followed infection by *Mycoplasma* [27], and a study in rats has suggested that adenovirus gene products in type II alveolar cells may be capable of promoting type I collagen formation [28].

Infectious causes aside, a case–control study has suggested that in up to about 20% of patients with the disease, exposure to wood or metal dust at work may have been an aetiological factor [29]; a recent British study of 588 patients has shown 47% to have had a history of a dusty occupation [30]. Recent work suggesting that the toxic effects of the ultra-fine fraction of particulate air pollution may lie in the transition metals on the particle surface (see Chapter 11) points towards what may be an interesting line of future research in this area [31]. Further evidence for an environmental factor comes from another case–control study in which it has been shown that cigarette smoking is a risk factor [32]. Another important clue to the aetiology is the occurrence of pulmonary fibrosis in rheumatoid and other collagen diseases. In the absence of the clinical manifestations of these diseases, rheumatoid factor and antinuclear factor are found in a proportion of patients with cryptogenic fibrosing alveolitis, suggesting a spectrum of response to whatever it is that causes these diseases. Again, the association of collagen diseases with quartz exposure [33] (see Chapter 54) serves as a reminder that these may also have environmental causes.

## Epidemiology

Cryptogenic fibrosing alveolitis is a disease affecting males rather more frequently than females, the median age at diagnosis being in the seventh decade. However it may occur in either sex at any age. The prevalence has been estimated, using somewhat different methods, to be about 6 per 100 000 in England and Wales and 20 per 100 000 in the USA [34,35]. It is the cause of some 2000 deaths annually in the UK and 10 000 annually in the USA. It appears to be becoming a more frequent cause of death

in the UK, Australia and Canada, and this may reflect a real rise in incidence as well as greater diagnostic awareness [21,23]. It seems to show no racial preference and is diagnosed in developing as well as developed countries [36].

## Pathology

In many patients with features suggesting a diagnosis of cryptogenic fibrosing alveolitis, a lung biopsy is carried out to provide both diagnostic and prognostic information prior to the initiation of therapy. Transbronchial lung biopsy is not suitable for establishing this diagnosis and open, trephine or, most frequently nowadays, thoracoscopic lung biopsy should be employed to obtain satisfactory tissue specimens [37–41]. There are two principal features of the disease identifiable on the biopsy: (i) cellular thickening of the alveolar walls with a tendency to fibrosis and (ii) the presence of large mononuclear cells within the alveolar spaces. The more prominent the second feature and the thinner the alveolar walls, the better the response to corticosteroid drugs [5,39,42]. In early disease, proliferation of type II alveolar epithelial cells and loss of type I cells may be seen [43]. The intra-alveolar mononuclear cells, once thought to be type II alveolar cells, are now known on the basis of ultrastructural and cytochemical studies to be predominantly alveolar macrophages [44–48]. Other cells, including lymphocytes, eosinophils, neutrophils and plasma cells, may be seen both in the interstitium and the alveoli. At an early phase, there may be fibrinous exudate in the alveoli with hyaline membrane formation. In the later stages, the lung architecture is distorted by fibrosis and there may be hyperplasia of the bronchiolar epithelium to line the residual airspaces. Interestingly, the collagen content of the lung does not differ from that found in controls but the ratio of type I to type III collagen is increased from 2:1 in controls to 4:1 in fibrosing alveolitis, reflecting increased production of type I collagen by the fibroblasts [49,50]. Release of fibronectin and alveolar macrophage-derived growth factor is not suppressed by corticosteroid therapy in these patients, which may explain the relatively poor response to such therapy [51]. Haemosiderosis and squamous metaplasia of bronchiolar and alveolar epithelium may occur [52,53], and occasionally deposits of bone may be found [54,55]. B-lymphocyte follicles with occasional germinal centres and containing helper T cells may be seen and indicate a local B-lymphoid immune response [56]. Occasionally when a particular cell type predominates, for example the lymphocyte, giant cell or plasma cell, the terms lymphocytic, giant cell or plasma cell interstitial pneumonia are used, although this differentiation is probably not clinically useful since all are likely to progress to end-stage fibrosis.

Livingstone and colleagues [57] divided their cases

**Fig. 31.1** Open lung biopsy from patient with a diffuse pneumonitis on radiography showing thickened alveolar walls lined by hyperplastic type II cells. The alveoli are filled with a mixture of macrophages and desquamated type II cells. This is the pattern of 'desquamative interstitial pneumonitis' (haematoxylin & eosin  $\times 150$ ).

pathologically into five grades according to the amount of disruption of lung architecture. Grade I is the mildest stage, in which change is confined to the alveolar walls, the alveolar spaces being empty. In grade II, the architecture of the lung is still intact, although the alveolar space is now filled with fluid or cellular exudate. In grade III, the alveolar architecture is becoming blurred and perhaps lost altogether, though bronchioles may still be recognized. Elastic fibre staining shows that the alveolar pattern is no longer intact. In grade IV, the normal lung structure is distorted by fibrosis, although remnants of bronchiolar epithelium and muscle may still be recognized. In grade V, the lung is converted to cystic spaces varying in diameter up to 1 cm or more. Grades IV and V commonly coexist and correlate with the presence of honeycombing on the chest radiograph, whereas grades I and II more often show

fine and coarse mottling on the chest film and a ground-glass appearance on high-resolution CT (HRCT).

The terms 'usual' and 'desquamative' interstitial pneumonitis have been used by pathologists to describe discrete pathological and clinical entities [6,58,59]. Most workers now consider 'desquamative' change to indicate the early stage of the disease with active alveolitis and minimal fibrosis (Fig. 31.1) and 'usual' change to indicate the late stage of the disease when fibrosis is established and alveolitis is minimal (Fig. 31.2) [1,60,61].

Injection studies have shown a dramatic increase in bronchial arteries with numerous precapillary bronchopulmonary anastomoses. In contrast, pulmonary angiograms show the peripheral pruning characteristic of pulmonary hypertension [62]. Pulmonary muscular hyperplasia may occur in some patients, resulting in

**Fig. 31.2** Open lung biopsy from patient with a familial type of interstitial lung disease showing expanded alveolar walls containing an interstitial infiltrate of chronic inflammatory cells and some fibrosis. A few hyperplastic alveolar lining cells are visible. This is the pattern of 'usual interstitial pneumonitis' (haematoxylin & eosin  $\times 150$ ).

pathological descriptions of 'bronchiolar emphysema' or 'muscular cirrhosis of the lung' [63–65]. Most such examples are probably variants of fibrosing alveolitis and radiologically honeycombing is common.

## Pathogenesis

The pathogenesis of cryptogenic fibrosing alveolitis is not understood. This statement is intended to prevent the reader feeling discouraged when confronted by all the trees and wondering where the wood is. After a promising start, most reviews of the subject finish as an enumeration of cytokines that may or may not be important, leaving the reader somewhat bewildered, as one might perhaps feel from trying to appreciate a symphony by studying small collections of notes played by individual instruments.

It may be helpful to think of the condition as an aberrant defensive reaction at the alveolar level, these defences having evolved specifically to deal with invading airborne microorganisms. The unknown initial stimulus, candidates for which have been discussed above, appears to initiate an uncontrolled inflammatory reaction that involves recruitment of macrophages, neutrophils and smaller numbers of other cells including lymphocytes, eosinophils and mast cells. This inflammatory reaction leads in turn to 'healing' by inappropriate alveolar wall fibrosis and destruction of the normal alveolar wall of type I and endothelial cells, with proliferation of type II cells, the normal progenitors of the type I cell. It is noteworthy that emphysema, which often accompanies fibrosis in sarcoidosis, allergic alveolitis and mineral pneumoconioses, is not a common feature of the cryptogenic disease but that late development of carcinoma is — this is the wood.

Whatever triggers the process, mystery number one, seems to be responsible for attracting the greatly increased numbers of alveolar macrophages, which in turn attract other inflammatory cells, leading to the alveolar wall damage. Mystery number two is why this process continues and is not checked, as it is in almost all infective alveolar inflammatory conditions. The answer to this is likely to be that the triggering stimulus remains *in situ*, perhaps as a consequence of virus-induced genetic change in epithelial or endothelial cells. This would be analogous to the pathogenesis of asbestosis, where the fibres remain embedded at alveolar level and continue to stimulate macrophage ingress, and consistent with bleomycin-induced fibrosis that generally arrests when the drug is stopped. However, another possibility is that the lungs in some people lose their ability to downregulate the inflammatory response, making them unable to control the process once initiated. This would be consistent with the studies of familial fibrosis and with the observation that the disease occurs only in relatively few of those people treated with bleomycin. It is possible, indeed likely, that

both mechanisms may operate together in those unfortunate enough to develop the disease.

Research intended to elucidate the pathogenetic mechanisms has studied both these possibilities. Less effort has been expended on what at first sight might appear more fundamental, the initial triggering factors and possible alterations in alveolar cells. The majority of the effort seems to have been devoted, perhaps understandably, to a search for cytokines that may be present to excess and therefore possibly amenable to drug therapy [66,67]. With respect to the former, the most promising research relates to alteration of cultured rat alveolar cells by adenovirus infection, leading to increased type I collagen production [28]. Viral alteration of the genetic material of alveolar cells could lead not only to uncontrolled fibrosis but also to the development of carcinoma, which is a feature of the condition.

The aspect of pathogenesis that has attracted most attention is the link between inflammatory cells, once recruited, and the deposition of fibrosis. Studies have concentrated on the demonstration of the actions of an increasingly large number of cytokines and cell receptors able to stimulate fibrogenesis, in the hope that an understanding of these mechanisms may lead to the development of drugs able to block them. Of the cytokines, those currently attracting most interest are transforming growth factor (TGF)- $\beta_1$  and tumour necrosis factor (TNF)- $\alpha$  [68]. TGF- $\beta_1$  has been shown to be able to cause expression of the gene for procollagen in fibroblasts, increase protein synthesis and inhibit breakdown of collagen. TNF- $\alpha$  has also been shown to cause increased collagen formation and is released in increased amounts from macrophages of patients with fibrosing alveolitis. In the case of both cytokines, there is experimental evidence that their fibrogenic action may be inhibited by antibodies, thus raising hopes of possible future therapeutic options [69,70]. Other cytokines that may play a part in fibrogenesis include platelet-derived growth factor and insulin growth factor 1. Endothelin 1, derived from capillary endothelial cells, may have a similar effect [71]. Finally, there is increasing interest in the presence of coagulation activity in the lung, based on the production by alveolar macrophages of thromboplastin and factor VII [72,73]. The very number of substances thought to be of interest in the genesis of lung fibrosis, and the fact that all are inflammatory cell products normally available and controlled by homeostatic mechanisms, indicate the difficulties that still lie ahead of those who hope to discover a curative treatment.

To pursue the symphonic analogy, the cytokines are the notes while the instruments are the inflammatory cells. Typically, in active cryptogenic fibrosing alveolitis, the total number of cells obtained at lavage is increased, with significant increases in percentages of neutrophils and eosinophils and occasionally a small increase in percentage of lymphocytes. Although the macrophage percent-

**Fig. 31.3** An outline scheme for the pathogenesis of cryptogenic fibrosing alveolitis. The initial stimulus to inflammation, acting through macrophage recruitment, and the reasons for uncontrolled progression to fibrosis are unknown.

age is usually decreased, the absolute numbers of macrophages are much increased [74–76]. A scheme, necessarily simplified, of some of the roles of each cell type in the pathogenesis of the disease is discussed below (Fig. 31.3).

### Alveolar macrophages

Not only are the alveolar macrophages increased in numbers in cryptogenic fibrosing alveolitis but the macrophages are activated, as demonstrated by increased surface expression of markers [77,78]. They have been shown to secrete a large number of cytokines, including interleukin (IL)-1, IL-6 and IL-12, interferon (IFN)- $\gamma$ , granulocyte-macrophage colony-stimulating factor (GM-CSF), TGF- $\beta$  and TNF. Mechanisms promoted by these substances are able between them to explain attraction and activation of further macrophages, neutrophils and lymphocytes [79–83]. However these mechanisms are all designed for anti-infection purposes and why they go awry in pulmonary fibrosis remains unknown.

### B lymphocytes

Although the percentage of lung B lymphocytes is not usually increased in cryptogenic fibrosing alveolitis, the absolute number is increased because the total number of lymphocytes is increased several-fold. B-lymphocytic fol-

licles with germinal centres have been identified in lung tissue from patients with cryptogenic fibrosing alveolitis [56] and the number of B lymphocytes producing immunoglobulin, particularly IgG, is increased [84]. In keeping with these observations, IgG levels in bronchoalveolar lavage (BAL) fluid of fibrosing alveolitis patients are increased, suggesting that there is active local production of immunoglobulins [85,86]. Coupled with the finding of immune complexes in BAL fluid, this suggests that immunoglobulins are produced locally in the lung and combine with antigens to form complexes that may subsequently be demonstrated both in the lung and in circulating blood. The antigen or antigens against which the antibodies are directed have not been identified but the observation that blood lymphocytes from patients with fibrosing alveolitis release lymphokines on exposure to type I collagen suggests one possible antigenic site in the alveolar wall [87].

### T lymphocytes

The percentage of T lymphocytes is not increased in BAL fluid of patients with cryptogenic fibrosing alveolitis but the absolute numbers are, under the control of macrophage-derived cytokines including IL-6 and IL-12. There is a suggestion that a shift from the Th1 subtype (which produces IFN- $\gamma$ , a cytokine that suppresses fibroblast proliferation and collagen synthesis) towards the Th2 subtype (which produces IL-4 and IL-5, both of which have been implicated in fibrogenesis) may be relevant to the production of fibrous tissue [88]. IL-5 is an eosinophil chemoattractant, and the presence of eosinophils in pulmonary fibrosis is an indicator of poor prognosis.

## Neutrophils

As already noted, the percentage and total number of neutrophils have been shown to be increased in BAL fluid of patients with fibrosing alveolitis, though not all studies are consistent in this respect [74–76]. However, tissue concentrations of these cells and evidence of their elastase activity are considerably increased from normal [89]. Their presence is probably a response to macrophage-derived attractants, including IL-6, IL-8, GM-CSF and TNF- $\alpha$ . When activated, they can perpetuate the inflammatory response by producing IL-1, IL-8, IFN- $\gamma$  and TNF- $\alpha$  themselves. These neutrophils are cytotoxic to normal lung parenchymal cells and their cytotoxic properties are related to the release of reactive oxidant species [90,91]. This is consistent with the demonstration of myeloperoxidase in BAL fluid of patients with the disease [92]. In addition, one neutrophil protease, a collagenase, has been found in lavage fluids from patients with the disease and shown to be cytolytic to normal lung explants [93,94]. The damage to alveolar walls may therefore be secondary to release of reactive oxidant species and proteases from neutrophils. The identification of fibronectin fragments in lavage fluid from patients with cryptogenic fibrosing alveolitis suggests that fibronectin degradation may also be occurring *in vivo* [95].

## Eosinophils

Eosinophils are often increased in percentage and total numbers in BAL fluid of patients with cryptogenic fibrosing alveolitis, attracted by macrophage-derived cytokines particularly IL-6. They may damage normal lung parenchymal cells by release of cytokines, including TGF- $\alpha$  and TNF- $\alpha$ , and also release a collagenase capable of cleaving types I and III collagen [94,96,97]. Their presence is generally taken to indicate a poor response to treatment.

## Conclusion

The pathogenesis of cryptogenic fibrosing alveolitis appears to hinge around activation of alveolar macrophages. The triggers of this reaction are unknown but could be infections, environmental pollutants or both. The activated macrophages produce chemotactic factors leading to accumulation of increased numbers of neutrophils and eosinophils which, by the generation of reactive oxidant species and proteases, produce local lung damage. The generation of cytokines promoting fibrosis by these cells and by lymphocytes promotes the collagenous scarring found in association with the lung tissue destruction characteristic of this disease. The condition is characterized by a failure of control

mechanisms that would normally be expected to halt the repair process, and this may have a partly genetic aetiology.

## Clinical features

Cryptogenic fibrosing alveolitis [1,3,30,53,57,98] is approximately twice as common in males and most commonly presents in older patients, the mean age in the largest survey reported being 67 years [30]. It commences in some 90% of patients with progressive dyspnoea on exertion. A non-productive cough is present in 75% at presentation. About 5% of patients are discovered at an asymptomatic stage by an incidental chest film or by a doctor hearing crepitations at the bases. The subacute, rapidly progressive type of the disease originally described by Hamman and Rich is much less common than the more slowly progressive chronic form of the disease, and may declare itself as an illness with systemic symptoms such as fever, weight loss, fatigue, myalgia and arthralgia

Finger clubbing is found in about half the patients, while auscultation of the chest reveals bilateral, gravity-dependent, inspiratory crepitations. With progression of disease, cyanosis becomes a feature and evidence of pulmonary hypertension may be found. In some patients, signs of connective tissue disease, such as rheumatoid arthritis, systemic lupus erythematosus or scleroderma, may coexist (see Chapter 53). Subgroups of patients with associated digital vasculitis or peripheral neuropathy have also been described [99,100], and rare associations with chronic active hepatitis and autoimmune haemolytic anaemia have been reported [101]. Hypertrophic pulmonary osteoarthropathy and spontaneous pneumothorax may occasionally occur [102,103]. Bronchogenic carcinoma is 14 times more common in patients with cryptogenic fibrosing alveolitis than in a control population [104]. In one series, carcinoma showed the usual distribution of histological types and was found in 13% of 155 patients followed to death [104].

The course of the disease is very variable. It ranges from an acute, rapidly progressive condition that may progress to death within months to a very slowly progressive or even apparently arrested pulmonary fibrosis. Most patients fall between these extremes and show gradual deterioration over 3 or 4 years. It is not uncommon in such circumstances to find that chest films taken several years before symptoms developed show early changes of fibrosis. In general, the younger the patient and the more acute the history, the more likely is the condition to respond to treatment. However, in an initial report of the large UK study 47% of patients had died within 2–4 years of enrolment, indicating a poor overall prognosis with or without treatment [30].

## Radiology

### Chest radiography

In the early stages the chest film can be normal despite the presence of dyspnoea. In one study of lung biopsies in breathless patients, 26% of 47 with a 'desquamative' histological picture had normal films compared with only 7% of 68 with the 'usual' type of alveolitis [105]. In the subacute type of disease, the initial chest radiograph may resemble bronchopneumonia with extensive patchy shadows, confluent in places, and more extensive in the lower zones (Fig. 31.4). In the commoner chronic type, mottling may give rise to a ground-glass appearance, although more often individual shadows up to 2 mm in diameter may be identified and these may later increase in size (Fig. 31.5). In the majority of patients the shadowing is predominantly in the lower zones. As the shadowing coarsens, translucencies up to 3 mm in diameter may appear, and this may finally develop into classical honey-comb lung (Fig. 31.6). Larger translucencies may also

occur and, in the later stages of the disease, emphysematous bullae and irregular streaky fibrosis may be seen [106]. Shrinkage of the lungs occurs, with progressive elevation of the diaphragms. In the presence of cor pulmonale the proximal pulmonary artery shadows increase in diameter.

When the disease is advanced, bronchograms may show shrinkage of the lung and bronchial dilatation. In the late stages, the distortion of lung architecture is reflected in bronchiolectasis and bronchial distortion [57]. In one reported case, diffuse dense mottled opacities seen on the chest film proved to be deposits of bone, some containing marrow cavities [55].

### Computed tomography

Because of the risks associated with lung biopsy and the generally poor response to treatment, non-invasive diagnostic methods find favour with most clinicians, especially in older patients. The dilemma regarding the decision to investigate has been made less taxing by the

**Fig. 31.4** Chest film of a female with a relatively rapid onset of pulmonary fibrosis. The patient presented with increasing breathlessness over 9 months. After 2 months of treatment with corticosteroids, the left lung remained unchanged but much clearing had occurred in the right lower zone.

**Fig. 31.5** Chest film of a patient with early fibrosing alveolitis showing diffuse, predominantly lower zone, micronodular infiltrates. This patient made a good response to corticosteroids.

advent of HRCT [107,108]. The features found on HRCT reflect histopathology quite well [109] and three types of shadow may be recognized. Early, active inflammatory disease is characterized by a ground-glass appearance,

**Fig. 31.6** Extensive honeycomb change in a patient with slowly progressing, irreversible fibrosis.

with hazy attenuation of the normal lung parenchyma but preservation of vascular shadows (Fig. 31.7). Usually such appearances coexist with areas of more mature fibrosis in the same film, and if biopsy is to be carried out it should be directed at an area of ground-glass opacity. As fibrous tissue is laid down, the appearances are of thickened interlobular and intralobular septa, giving a reticular pattern

**Fig. 31.7** High-resolution CT of patient with predominantly 'desquamative' alveolitis, in this case associated with rheumatoid disease, showing patchy ground-glass appearances. (Courtesy of Dr Lesley Gomersal.)

**Fig. 31.8** High-resolution CT of patient with 'usual' type of fibrosing alveolitis showing reticular pattern of interlobular and intralobular fibrosis. (Courtesy of Dr Lesley Gomersal.)

(Fig. 31.8); the distribution of shadows is predominantly lower zone and subpleural initially, though as the disease progresses it becomes more generalized. Finally, mature fibrosis with bronchial ectasia and destruction of lung architecture is represented by thick-walled cystic changes 5–10 mm in diameter, so-called honeycombing (Fig. 31.9). In smokers, emphysematous changes in the upper zones often coexist with the fibrosis [110].

These appearances are reasonably characteristic and, taken with the clinical features, allow a confident diagnosis to be made in most cases. They do not differ in any important respects from the changes seen in systemic sclerosis or asbestosis, although the differentiation from these diseases is made on other clinical grounds and, in the case of asbestosis, by the frequent presence of associated pleural lesions. In younger patients, differentiation from the rare diseases, Langerhans' cell histiocytosis and lymphangioleiomyomatosis, is aided by the more generalized appearances, nodular change and thinner-walled cysts in these conditions.

### Gallium-67 lung scanning

Pulmonary uptake of gallium occurs in many diffuse interstitial lung diseases, including cryptogenic fibrosing alveolitis [76]. The pattern of uptake is usually diffuse and confined to the lung parenchyma. Such scans are positive in about 70% of all patients with cryptogenic fibrosing alveolitis [76,98], and the intensity of gallium

**Fig. 31.9** High-resolution CT of patient with advanced disease showing honeycomb pattern of fibrosis with destruction of normal lung architecture. (Courtesy of Dr Lesley Gomersal.)

uptake correlates well with the degree of alveolitis on open lung biopsy and the percentage of polymorphonuclear leucocytes present in BAL fluid [111]. However, this technique does not make a major contribution to the clinical assessment of patients with cryptogenic fibrosing alveolitis.

## Pulmonary function

The lung volumes may be normal in early cryptogenic fibrosing alveolitis but as the disease progresses all the compartments of lung volume decrease, with a relatively greater reduction in vital capacity [98,112,113]. In the absence of extensive emphysema the forced expiratory volume in 1 s ( $FEV_1$ )/forced vital capacity (FVC) ratio is normal, although abnormalities in sophisticated tests of small airways function (e.g. frequency dependence of compliance, the terminal portion of the maximum expiratory flow–volume curve and the maximum flow–static recoil curve) correlate with morphological evidence of small airways disease [114,115].

The single-breath diffusing capacity for carbon monoxide is reduced early in cryptogenic fibrosing alveolitis [76,112]. In the early stages of the disease,  $Pao_2$  may be normal at rest but falls during exercise when the alveolar–arterial  $PO_2$  gradient is increased [76,116–119]. With progression of disease, resting hypoxaemia develops. The major part of this hypoxaemia can be explained by mismatching of ventilation and perfusion [120–122]. During exercise, because of the reduced transit time of erythrocytes in the pulmonary capillaries, up to 20% of the exercise-induced widening of the alveolar–arterial  $PO_2$  difference may be due to impaired oxygen diffusion [123]. Hypoxaemia in fibrosing alveolitis worsens during sleep, particularly in the rapid eye movement stage [119,124].

Lung compliance is reduced in fibrosing alveolitis, with greater transpulmonary pressure changes on breathing and consequent increase in the work of breathing, which may be responsible for the sensation of dyspnoea. Exercise tolerance is reduced and there is an increased heart rate and ventilatory response to exercise compared with normal individuals [125]. The maximal achievable exercise ventilation correlates with lung volumes. The tidal volume is reduced in proportion to the reduction in vital capacity and increased ventilation during exercise is achieved by increases in respiratory rate rather than by the predominant increase in tidal volume seen in normal subjects [125,126]. The 12-min walking test provides a useful measure of limitation of exercise tolerance in these patients [127].

## Bronchoalveolar lavage

BAL fluid usually shows an excess of neutrophils and eosinophils compared with normal non-smokers. There is considerable overlap, making this little use as a diagnostic test; it is more informative in a prognostic sense, in that high proportions of neutrophils (>4%) or eosinophils (>3%) are indicative of a poor response to steroids. A relative lymphocytosis (>11%) may also be an indicator of active alveolar inflammation and a better response to steroid treatment [128,129].

## Other investigations

The erythrocyte sedimentation rate is usually elevated in this disease, but apart from the occasional detection of antinuclear antibodies, rheumatoid factor, cryoglobulins or other autoimmune phenomena, no other abnormalities are found in the peripheral blood [98,130,131].

## Diagnosis

The diagnosis is suggested by the clinical features of dyspnoea, cough and bilateral basal crepitations in an elderly or middle-aged individual, the presence of reticulonodular shadowing predominantly at the lung bases on the chest film in the absence of a known cause, the typical findings on HRCT, and appropriate pulmonary function findings. In most cases these investigations are sufficient to make a confident clinical diagnosis, although differential cell counting of BAL fluid may assist in indicating likely response to treatment. The main decision required is whether to proceed to lung biopsy, which provides definitive proof of the diagnosis and somewhat better prognostic evidence. It has been established that the small specimens obtained by transbronchial biopsy through the fiberoptic bronchoscope are not suitable [37] and open or thoracoscopic lung biopsy, guided by HRCT to areas of active alveolitis if present, is preferred [37–41]. This therefore subjects the patient to some risk and discomfort and should be undertaken only if it is considered that knowledge of the histological appearances would influence the physician's treatment regimen. Thus the serious possibility of some other disease, more acute presentations or a relatively young patient in whom a very persistent trial of treatment, often including consideration of transplantation, is likely to be considered are usually influential factors in coming to a decision to proceed to biopsy. With appropriate ethical safeguards, biopsy would also usually be advised if the patient has agreed to participate in a trial of new therapy. Physicians differ in their practices but ultimately rather fewer than half of all patients are biopsied in the UK. In the majority of patients the clinical findings, including HRCT, give sufficient diagnostic information to justify a therapeutic trial monitored by response in terms of change in lung function. However, patients with an acute or rapidly progressive presentation in whom HRCT suggests active disease should almost always have early biopsy if considered fit enough, since the differential diagnosis of such patients is wide and treatment may well be influenced by the histological findings.

## Treatment

It is disappointing to record that the prognosis of this condition appears not to have altered appreciably nor has any important advance in treatment occurred since the first

edition of this book in 1969. The mainstay of therapy in cryptogenic fibrosing alveolitis remains corticosteroids, prednisolone being the drug of choice. Since occasionally the disease is very slowly progressive, or has even arrested, it is wise in patients suspected of such a course to allow a period of several months to elapse, monitoring the patient's lung function and exercise performance carefully in order to assess whether treatment is likely to be necessary. In fact, the major recent UK study showed that the option not to treat was taken in over 50% of cases [30]. After the diagnosis has been established and baseline measurements of pulmonary function (i.e. lung volumes, *DLCO* and exercise tolerance) have been obtained, treatment is usually initiated with prednisolone in a dose of 40–60 mg daily for at least 4 weeks. This is followed by a graduated reduction in dosage over 2–3 months to the lowest maintenance dose capable of sustaining any objective improvement in chest radiograph, lung volumes, exercise tolerance or *DLCO* that has been achieved. Objective improvement is most likely to be found in those with histological evidence of early disease with marked cellularity and little fibrosis on the lung biopsy [6,39], in younger patients and in those with recent onset of disease [39,132], and in those with less severe radiographic and functional abnormality [132].

Although it is common (almost 60% in one series [133]) for patients to report some subjective improvement with corticosteroid therapy, objective evidence of improvement is found relatively rarely (17% in the same study). Clearly, many patients with established fibrotic disease do not respond, although a trial of therapy is often warranted. BAL studies suggest that high eosinophil or neutrophil counts or low lymphocyte counts predict a poor clinical response to corticosteroids, whereas a lymphocyte count of greater than 11% appears to be related to improvement [128,134–136]. Serial lavage studies suggest that objective improvement is associated in general with return of elevated cell counts towards normality; however, there is no indication at present that such studies, although interesting from the research point of view, influence the clinical management of patients [136]. Indeed, striking decreases in neutrophil counts in BAL fluid occasioned by high-dose parenteral steroid therapy have resulted in no greater changes radiologically and functionally than occurred in a conventionally treated group [137]. Also, confusingly, corticosteroid therapy may lead to an increase in lavage neutrophils in smokers with fibrosing alveolitis [138].

In patients who do not respond to corticosteroids or for whom steroid therapy is contraindicated, immunosuppressant drugs such as azathioprine 150 mg daily or cyclophosphamide 100–120 mg daily may be tried. There have been reports of successful treatment with these agents, which may also be employed for their steroid-sparing effect [136,139,140]. Patients treated with a combi-

nation of cyclophosphamide or azathioprine and prednisolone fare little if any better than those treated with prednisolone alone [141,142], although there is a case for considering such a combination for its steroid-sparing properties. No other drugs have proved of clinical value, but it is to be hoped that the new understanding of pathogenetic mechanisms discussed above will lead to therapeutic trials of specific cytokine antibodies or receptor antagonists that may eventually prove of more promise. Possible new therapeutic options have been discussed in detail [67,68].

The author's approach is to make an initial assessment of likelihood of response, based mainly on HRCT and either biopsy or BAL findings. In the presence of evidence of active alveolitis, combined steroids and cyclophosphamide are started immediately and continued until it becomes apparent that no physiological response is occurring or side-effects become intolerable. In the absence of such evidence, a judgement is made as to whether treatment is justified after several months of follow-up with repeated lung function and exercise tolerance tests. Old radiographs are particularly helpful in assessing progression if they are available. The patient's age and general condition are also taken into consideration; most important are the views of the patients themselves, after explanation of the chances of response, the likely prognosis and the side-effects of treatment. Many older patients prefer to wait and see when presented with this information.

In younger non-smoking patients without systemic disease, there is now the option of lung transplantation [143,144] (see Chapter 59) and pulmonary fibrosis is responsible for 20% of transplants done currently [145]. The results indicate a 50% survival at 3 years [146].

Since only a small minority of patients with chronic disease respond in any worthwhile way to steroids or immunosuppressants and many find the side-effects of the former intolerable, the drugs are usually discontinued after a trial of several months and (except in younger patients intended for transplantation) efforts should be made to relieve the symptoms as far as possible. In some cases, small doses of benzodiazepine may help relieve the intractable breathlessness. In the later stages of the disease, oxygen therapy and treatment for right heart failure may be required. Appropriate sedation with opiates should be given in the terminal stages of the disease to relieve the intense distress occasioned by dyspnoea.

## Prognosis

The duration of the illness is variable but may range from a few months in patients whose disease follows a fulminant course to over 20 years. In several large series the average duration of survival from diagnosis has been 4–5 years [39,57,133]. Carrington and colleagues [6] found

5-year mortality in the 'desquamative' type of disease to be 27.5% with a mean survival of 12.2 years compared with 66% and 5.6 years in the 'usual' type. Only the 'desquamative' type improved spontaneously (22%). With corticosteroid drugs, 61.5% of the 'desquamative' but only 11.5% of the 'usual' type improved. In Stack's series the 5-year survival was 43% in those responding to corticosteroids compared with only 20% for those who did not respond [147]. As already mentioned, survival is longest in those with the most cellular and least fibrotic lung biopsies. Wright and colleagues [39] showed that patients with little fibrosis on lung biopsy had a 5-year survival of 90% compared with a 25% 5-year survival in those with severe fibrosis on biopsy. Most patients die from respiratory or cardiac failure, although there is a significant excess of lung cancer in patients with cryptogenic fibrosing alveolitis [104].

## Differential diagnosis of diffuse interstitial lung disease

Contrary to the impression conveyed by accounts of the differential diagnosis of diffuse interstitial lung disease (Table 31.1), the diagnosis of the usual type of cryptogenic fibrosing alveolitis is quite straightforward. A good history and examination, coupled with some experience of the more usual radiographic and HRCT appearances of given diseases makes the task of differential diagnosis easy. The most important aspect of diagnosis is to exclude both more readily treatable causes of the radiological appearances and also conditions with different prognoses. Thus, in practice, sarcoidosis, pneumoconioses (especially asbestosis), extrinsic allergic alveolitis and, most importantly, adverse reactions to drugs need to be considered. The more acute form of the disease, with ground-glass HRCT appearances, has a wider differential diagnosis that is usually only resolved by lung biopsy, a procedure that should not be delayed in such cases.

## Clinical features

### History

Cough productive of sputum is suggestive of airway involvement, and diffuse shadowing on the chest film with associated cough and purulent sputum would suggest pneumonia in relation to underlying airway disease, such as might be found in chronic bronchitis, bronchiectasis and cystic fibrosis. Cough with purulent sputum may also be features of allergic bronchopulmonary aspergillosis, tuberculosis and chronic eosinophilic pneumonia.

Wheeze is a usual accompaniment of acute allergic bronchopulmonary aspergillosis and chronic eosinophilic

pneumonia and is also found in the pulmonary vasculitides and pulmonary oedema. Dyspnoea is a common presenting symptom in diffuse interstitial lung disease. When acute in onset and associated with fever, infection should be suspected although in some instances a connective tissue disorder such as disseminated lupus erythematosus is responsible. Acute dyspnoea is of course commonly due to left ventricular failure. Episodic acute dyspnoea is a feature of extrinsic allergic alveolitis, when a history of exposure to the relevant antigen will be obtained and influenza-type symptoms may be associated. Slowly progressive rather than acute dyspnoea suggests a chronic progressive disease. The rate of progression of dyspnoea varies widely between different processes. Slow progression over a decade or more is usual in asbestosis and some other pneumoconioses and is also found in pulmonary sarcoidosis evolving to fibrosis. In contrast, in some of the complications of human immunodeficiency virus (HIV) infection, including *Pneumocystis* pneumonia, or the more acute cryptogenic fibrosing alveolitis, dyspnoea may progress more rapidly, often over a few months. The relative severity of dyspnoea in relation to the radiographic extent of disease is also important, for example sarcoidosis may cause minimal dyspnoea despite substantial radiographic extent of disease, whereas in cryptogenic fibrosing alveolitis dyspnoea may be disproportionately severe.

Chest pain of a pleuritic nature may suggest a diagnosis of connective tissue disease or pleural involvement in, for example, rheumatoid arthritis or sarcoidosis. Acute pleuritic pain due to pneumothorax may be consequent on rupture of bullae or blebs in chronic fibrotic processes, such as cryptogenic fibrosing alveolitis, or be a manifestation of less common diseases, such as Langerhans' cell histiocytosis or lymphangioleiomyomatosis.

Haemoptysis may occur in left ventricular failure and is a feature of less common conditions such as idiopathic pulmonary haemosiderosis and Goodpasture's syndrome.

As is apparent from Table 31.1, an occupational and environmental history is of cardinal importance. Not only the present occupation but previous occupations should be documented and explored for possible exposure to inhaled agents. If necessary, the workplace should be visited and possible agents obtained for challenge tests if indicated. A domiciliary visit may be required in some cases. The author has seen extrinsic allergic alveolitis in a patient who persistently denied keeping birds until a home visit revealed the offending budgerigars, which an astute ward sister had overheard twittering during a telephone call from the patient's husband. In a similar case, bird fanciers' lung was diagnosed in a patient who eventually revealed that he was keeping doves in his kitchen.

A drug history should be vigorously pursued. Many cytotoxic drugs cause pulmonary fibrosis. Nitrofurantoin, still frequently prescribed for recurrent urinary tract infections, and sulfasalazine (sulphasalazine) for ulcerative colitis are not uncommon causes of pulmonary eosinophilia or chronic progressive fibrosis. The problems of differential diagnosis of diffuse pulmonary shadowing in the immunosuppressed host are discussed in Chapter 52.

Extrapulmonary symptoms may suggest systemic disease. Arthralgia and skin lesions are found in sarcoidosis, connective tissue disease and Wegener's granulomatosis. Eye and skin symptoms are common in sarcoidosis and upper respiratory tract symptoms in Wegener's granulomatosis. Bone lesions may be found in Langerhans' cell histiocytosis and chronic sarcoidosis. Increasingly in the UK, and to a much greater extent in Africa and parts of Asia and the USA, it is necessary to consider HIV infection as a cause of interstitial lung disease, either infective or infiltrative, and some of these manifestations, such as *Pneumocystis* infection or lymphocytic interstitial pneumonitis, cause diagnostic difficulties. A history designed to elicit risk factors and HIV testing should now be considered in all patients with diffuse lung disease of obscure aetiology.

### Examination

Finger clubbing is a feature of cryptogenic fibrosing alveolitis and asbestosis and may also be found in bronchiectasis and cystic fibrosis. Bilateral crepitations on auscultation are a feature of pulmonary oedema, cryptogenic fibrosing alveolitis, extrinsic allergic alveolitis and asbestosis. Crepitations are not a feature of the other pneumoconioses or sarcoidosis (except in the late fibrotic stages). A full examination of all systems should be undertaken in a search for relevant signs, with particular attention being paid to bones and joints, the skin and the eyes.

### Other investigations

The routine full blood count may be diagnostically useful. A neutrophil leucocytosis suggests bacterial infection, while eosinophilia is found in pulmonary eosinophilia of whatever cause (see Chapter 38). A very high erythrocyte sedimentation rate may be found in connective tissue diseases, Wegener's granulomatosis, Goodpasture's syndrome and in chronic eosinophilic pneumonia. Sputum examination may reveal bacterial or fungal infection or malignant cells. Iron-laden macrophages are found in the sputum in idiopathic pulmonary haemosiderosis and PAS-positive material in alveolar proteinosis. Sputum eosinophilia may suggest pulmonary eosinophilia and

bronchial casts may be found in allergic bronchopulmonary aspergillosis.

Precipitins to the causative antigen may be detected in extrinsic allergic alveolitis. Antinuclear antibodies and anti-DNA antibodies are found in disseminated lupus erythematosus; antinuclear and rheumatoid factors may also be found in cryptogenic fibrosing alveolitis and antineutrophil cytoplasmic antibodies in Wegener's granulomatosis. Serological evidence of HIV infection should be sought where relevant and after appropriate discussion with the patient.

BAL may be of value in diagnosing infection and differential cell counting may suggest diagnoses of fibrosing alveolitis, extrinsic allergic alveolitis or sarcoidosis. Birbeck (or X) bodies may be found in Langerhans' cell histiocytosis, and evidence of HIV-related infection may be found with appropriate stains. Transbronchial biopsy is of value in diagnosing infection, malignancy, alveolar proteinosis, haemosiderosis and sarcoidosis but open lung biopsy may be necessary to establish a firm diagnosis particularly in cryptogenic fibrosing alveolitis.

Chest radiograph

The radiographic appearances of specific conditions are described in detail in the relevant chapters. In many conditions the distribution of pulmonary opacities is characteristic and examples of generalized, upper, middle and lower zone opacities are listed in Table 31.2.

Table 31.2 Patterns of distributions of pulmonary opacities on the chest radiograph.

Upper zones
Tuberculosis
Chronic sarcoidosis
Extrinsic allergic alveolitis
Langerhans' cell histiocytosis
Subacute silicosis
Progressive massive fibrosis
Middle zones
Pulmonary oedema
Alveolar proteinosis
<i>Pneumocystis carinii</i> infection
Lower zones
Cryptogenic fibrosing alveolitis
Asbestosis
Bronchopneumonia
Collagen diseases
Tropical eosinophilia
Generalized
Pneumoconioses
Miliary tuberculosis
Sarcoidosis
Cystic fibrosis
Complications of human immunodeficiency virus infection
Metastases
Lymphangitic carcinomatosis
Adult respiratory distress syndrome
Drug reactions
Haemosiderosis
Microolithiasis

# ASTHMA: EPIDEMIOLOGY

PETER G. J. BURNEY

Asthma is an important condition with a very variable prevalence that has become an increasing burden on health in both developing and market economies. The condition is associated with atopy, although its causes are otherwise poorly understood. Most people with asthma have mild disease with occasional exacerbations but some develop chronic airflow obstruction and patients with diagnosed asthma have a reduced expectation of life.

## Definition and presentation

Asthma remains undefined. In 1958 a CIBA guest symposium set out to define chronic lung diseases and provided a definition of asthma as 'the condition of subjects with widespread narrowing of the bronchial airways which changes its severity over short periods of time either spontaneously or under treatment' [1]. This remains the benchmark definition, and several groups have refined or altered it to suit current hypotheses from time to time. However, it was pointed out soon after the publication of the symposium that this was less a definition than a description of the condition [2]. A true definition provides unambiguous criteria for deciding whether an individual has asthma or not. Despite this we are no nearer a definition and one recent attempt is perhaps even vaguer than the original on which it is based:

a chronic inflammatory disorder of the airway in which many cells play a role, including mast cells and eosinophils. In susceptible individuals this inflammation causes symptoms which are usually associated with widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment, and causes an associated increase in airway responsiveness to a variety of stimuli [3].

Because asthma is used to convey a complex idea, a simple definition is probably not possible and clarification has generally come through restricting the use of the term. For instance, 'renal asthma', a term used at the beginning of the century, is now not recognized and it is increasingly archaic to talk of 'cardiac asthma'. The utility of discussing

all obstructive lung disease as a spectrum of disease with common aetiology (the Dutch hypothesis) is still debated [4]. Against the hypothesis, smoking and atopy are independent risk factors for bronchial hyperresponsiveness and appear to have their effects through different mechanisms [5,6]. The hyperresponsiveness associated with cigarette smoking only emerges in middle life and is more strongly associated with low lung function, whereas the hyperresponsiveness associated with atopy is seen much earlier in life. A number of people develop a condition very similar to atopic asthma, although they are not atopic in the conventional sense of having specific IgE to common inhalant allergen. Nevertheless these 'intrinsic asthmatics' have a histology similar to that of atopic asthmatics and it is speculated that the mechanisms are also similar [7].

In studying asthma, working definitions are required and a number of inconsistent methods have been used; the most common are given in Table 32.1. A clinical diagnosis of asthma is often used in clinical research. However, there is evidence for important differences, at least between countries, in the way that doctors identify patients with asthma [8], and the implicit lack of standardization in this method is unacceptable in epidemiological studies even when the study is small enough for the method to be feasible.

Patients' own reports of whether they have asthma are closely related to their reports on taking treatment for asthma and are largely determined by a doctor's diagnosis. This therefore has the same problem of poor standardization. In addition patients may not always know the doctor's diagnosis [9], and the diagnosis depends on the accessibility and quality of the local health services. This is a particularly severe restriction where surveys are being used in part to assess the quality of healthcare.

Questions concerning symptoms are less prone to these problems and as such are preferable, though they also have their limitations. There is no clear-cut symptom or symptom complex that is pathognomonic of asthma [10] and perception and reporting of symptoms

**Table 32.1** Common methods for identifying asthma in surveys.

Indirect: cold air, exercise, adenosine
Bronchial response to bronchodilators
Bronchial response to steroids

---

may be affected by a number of psychological and cultural factors. Nevertheless there are now some well-standardized, symptom-based questionnaires that can be used [10–12].

Where questionnaires are potentially cheap and quick, physiological measures tend to be expensive to undertake in large surveys. Nevertheless they are less open to cultural influences and are a useful adjunct in epidemiological surveys. Once again, however, there is no physiological measure that is pathognomonic of asthma as it is generally understood and the different tests do not give closely related answers [13].

Improved lung function following administration of a bronchodilator is a useful clinical test but is probably less useful in surveys where 'asthmatic' subjects may have good lung function prior to the medication and therefore may not respond.

Bronchial challenge tests using bronchoconstrictor agents are now commonly used in surveys and simplified dosage schedules have been introduced [14]. Indirect challenge with cold air, non-isotonic saline, exercise or adenosine may be more specific for asthma, although there is less experience with adenosine in large surveys and standardization of the other methods is even more difficult. Extensive use has been made of histamine and methacholine challenge in surveys and there is now a great deal of experience with these. However, patients with cigarette-induced airway damage also respond to these tests. Challenge tests also tend to be relatively poorly standardized, as the effective dose delivered depends on the nature of the aerosol and this may vary considerably from one machine to another. Using the slope of the dose-response curve as the measure of responsiveness mitigates this problem and has the additional advantage that it provides a continuous measure of responsiveness [15].

In reality, the distinction between the normal and the abnormal is somewhat arbitrary and the level of abnormality selected as being significant is as important as the method of detection. In general it can be shown that specific tests give less misclassification, while the best test depends on the circumstances in which it is being used

and on the prevalence of disease in the population under study.

## Distribution

### Geography

Asthma is widely distributed but very variable in its prevalence. The use of standardized methods ensures that even though the absolute prevalence of the disease is unknowable, because the disease is undefined, the relative prevalence of the condition can be studied. It appears from surveys of children [16,17] and young adults [18] that the disease is more common in the English-speaking world and in some other areas such as France, of relatively lower prevalence in Scandinavia and in most of southern and eastern Europe, and very low in prevalence in some parts of rural Africa and other areas with markedly undeveloped ways of life [19–22]. There is some broad correlation between the prevalence of asthma and the prevalence of IgE antibodies to common inhaled allergens [23].

### Age and sex

The incidence of diagnosed asthma as recorded in the USA is highest in the first year of life. In childhood the incidence is higher in boys than girls but reverses in the age group 15–50 years and reverses again in the older age group when the incidence among men increases once more [24]. The prevalence of bronchial responsiveness has been shown to follow a similar pattern, with boys having greater responsiveness than girls but adult women having higher levels than men and older men having similar levels of hyperresponsiveness as older women [25].

Women have lower levels of total and specific IgE than men and cross-sectional surveys show an increase in prevalence of sensitization during childhood and a marked decline with age in adult life [26,27]. However, cohort studies suggest that at least part of this later decline is due not to ageing but to the year of birth, implying that people who were born longer ago were less likely to become sensitized in the first place [28].

### Ethnicity

Differences in atopy and asthma have been reported between different ethnic groups but whether these are due to genetic, environmental or cultural differences is unclear.

In the UK, there is greater respiratory morbidity in inner city areas, particularly among Afro-Caribbean and white children, although Afro-Caribbean children report slightly less asthma [29–31]. Black British and Caribbean children have also been found to have more atopic dermatitis [32,33], though in one of the surveys this was not

true of black children from Africa [33]. In the USA, both serum IgE levels [34] and the prevalence of skin sensitivity [26] are slightly higher in African-Americans. Schwartz and colleagues [35] also found a significantly increased prevalence of diagnosed asthma (and to a lesser extent wheeze) in black children in the NHANES II study.

By contrast, in Southern Africa there was no difference in the prevalence of exercise-induced bronchoconstriction between black and white children living in the affluent northern suburbs of Harare [22].

In the UK, children from the Indian subcontinent tend to report fewer symptoms [36–38] but have been estimated to have either a greater prevalence of exercise-induced responsiveness [37] or equal prevalence of methacholine-induced responsiveness and a greater prevalence of atopy [38]. They have also been reported to have an increased tendency to respond to food additives, particularly fizzy drinks [39].

In New Zealand [40], European children have a higher prevalence of bronchial responsiveness than the Maoris, who in turn have a higher prevalence of responsiveness than the Pacific Islanders. However the Maoris report more symptoms than either the Europeans or Pacific Islanders. In young adults the Maoris also report more symptoms, though this is largely due to higher prevalence rates in those aged 30–44 years and the Maoris have lower rates of hay fever and are heavier smokers than the Europeans, suggesting that their increased symptoms may not be due to asthma.

### Poverty/social status

The relation between poverty and wheezing is strongly confounded by exposure to cigarette smoke. Children from the 1958 birth cohort whose fathers were of higher social class were more likely to have hay fever and atopic dermatitis [41] and were more likely to be sensitive to common allergens at 33 years old [42], though there was no association with wheezy illness at that age when other factors had been taken into account [43]. The children of fathers of higher social class studied in the 1970 birth cohort were more likely to have persistent wheeze at the age of 16, though they had had less wheeze at the age of 5 [44]. Much of the excess risk of asthma in Baltimore could be explained better by poverty than by ethnicity alone [45]. In England and Wales more severe asthma has also been reported among adults from lower social classes [46].

### Time

There is good evidence that the prevalence of wheezy illness has been increasing over the last couple of decades at least. Indirect evidence suggests that this may have been happening in some places from the early part of the

century, at least in those countries with high prevalence rates. It appears that this has been accompanied for the most part by changes in the prevalence of other atopic conditions [47,48] and in the prevalence of sensitivity to common aeroallergens [49,50]. It would be natural to conclude that much of the increase was secondary to this change in the prevalence of atopy. However it is likely that other factors are also involved and these would have to explain the changes in Australia, where there is evidence for an increasing prevalence of asthma but for a constant prevalence of atopy as measured by skin tests [51].

Admissions to hospitals with asthma have been increasing at approximately the same rate as the increase in the prevalence of disease. There is good reason to believe that hospital admission rates are affected by both health service factors and local prevalence rates [52,53], and the recent slowing down in the increase of admission rates in several countries may be due to health service pressure on costs and, in particular, financial pressure to reduce the use of inpatient facilities [54,55].

The major changes in mortality during the latter half of the twentieth century probably have little to do with changes in prevalence, although it is likely that mortality rates have been affected by changes in prevalence and this may be what is implied by the weak cohort effects found in mortality trends [56]. The changes in prevalence that have almost certainly occurred make it difficult to assess any long-term changes in the case fatality of the disease. Although evidence from life assurance companies, mostly in the USA, suggests that these have been relatively constant over the century, their interpretation is difficult [57].

Although the changes reported here are widespread, it should not be assumed that they have been universal. Trends are more likely to be studied where there is a prior belief that the rates are rising. Only a more systematic estimate of trends would allow generalizations to be made about such changes. The question of whether the same upward trends in prevalence are continuing is difficult to answer.

### Early life

There are several characteristics of early life that predict atopy and asthma later in life. However, it is possible that these are, at least in some cases, predictors of continuing exposures that also persist into adult life. In the case of asthma at least, there is evidence for continuing plasticity as evidenced, for instance, in the effect of migration. In the UK, where there is regional variation in the prevalences of wheezy illness, children at the age of 5 or 7 years have prevalences of wheezy illness closer to those of the regions to which they have migrated than to those in the regions where they were born [58].

There are consistent reports that children from larger

families have less hay fever and atopy than those from smaller families. There is more debate as to whether this is an effect of large families or whether it is more specifically related to the number of older siblings. This finding has not generally been replicated when looking at the prevalence of asthma [59], although Seidman and colleagues [60] have described a similar relationship for asthma in Israeli military recruits.

Younger mothers have been noted to have infants with more wheezy lower respiratory tract infections [61] and 3–4 year olds with more asthma [62]. In the 1970 British birth cohort, children at the age of 16 were more likely to have persistent wheeze if their mothers were younger, but this was not the case at the age of 5 nor was it the case in the 1958 birth cohort. On the other hand, adolescents in Sheffield were found to have rather less hay fever if their mothers were younger [63].

Children who are born prematurely have a greater prevalence of sensitization to allergens [64]. They are also more likely to have wheezy illness [35,65,66] and asthma [67] at primary school age. However, prematurity was not associated with wheezy illness in either the 1958 [43] or 1970 [44] birth cohorts and Olesen and colleagues [68] concluded that atopic dermatitis was more common in postmature children. Bertrand and colleagues [69] hypothesized that both children who were born prematurely and their mothers might be more likely to have airway hyperresponsiveness, though others [70], while confirming the association between low birthweight and later airway responsiveness, were unable to link this with maternal airway responsiveness.

Low birthweight children have been reported to have a greater risk of having asthma and wheeze in childhood [35,70], asthma or wheeze at 16 [71] and asthma as young adults [60] and a lower lung function as primary school children [65] and adults [72]. However, others have reported no greater risk of asthma in childhood [65,67,73] and a reduced risk of atopic dermatitis in low birthweight babies [68].

## Exposure to allergens

Exposure to allergen is necessary for sensitization and for subsequent expression of disease, although as allergens are widespread other factors may well be more important in determining whether sensitization takes place. Some studies have shown that sensitivity to house-dust mite is rare among children where antigen levels are less than 2 pg/g of dust but is increasingly likely as levels rise above this value [74,75]; areas with low levels of dust mite antigens have low prevalence of sensitivity to the allergen [76,77]. Studies have also suggested that cat ownership is associated with sensitization to cats in children [64,78]. However, others have shown very little relation between domestic levels of allergen and sensitivity to mites [79,80]

or cat [79] and Rugtveit [81] was unable to find an association between pet ownership and sensitization to cat or dog.

There is considerable interest in the possibility that early exposure to allergen may be particularly important. The evidence for this is based largely on the association between sensitization to particular allergens and month of birth. A number of studies have shown a strong association between mite allergen sensitivity and birth in the latter part of the year [82–85]. However, in the UK at least, mite is not a strongly seasonal allergen, and there is only very inconsistent evidence that pollen allergen is related to month of birth.

It is unlikely that increased exposure to allergen has led to the increase in sensitization mentioned earlier. Although insulation of housing has increased and it has been shown that reduced ventilation leads to increases in levels of both cat [86] and mite [87] allergens in the home, the two studies that have documented increases in sensitivity to allergens [49,50] have shown that the increase is not due to increases in indoor allergens alone and there is little evidence for an increase in other allergens [88].

Exposure of sensitized subjects to allergen increases bronchial reactivity and this increase is associated with the late asthmatic response [89]. In the USA the increase in emergency room visits with asthma that occurs in the spring has been associated with raised IgE to grass pollen allergen [90] and several studies have shown an association between indoor mite allergen levels and clinical disease [80,91]. There is further evidence that acute severe asthma may be associated with exposure to high ambient levels of indoor allergen [92].

Epidemics of asthma are rare but those that have been recorded have mostly been associated with allergen. The best documented of these were the epidemics of asthma in Barcelona associated with the release of soybean allergen [93]. Other epidemics have been associated with castor bean allergen [94,95] and possibly grass allergen released from pollen during thunderstorms [96,97].

Mortality among young asthmatics also shows a seasonal variation and this is particularly marked in those who die suddenly [98,99]. Increases in acute severe asthma and asthma deaths have been reported following exposure to moulds [100–102] and to soybean dust [93]. The role of indoor allergen in asthma deaths is poorly understood.

## Smoking

Smoking has frequently been associated with higher levels of total serum IgE [103–106]. Although adjustment for age and gender, which are important confounders, reduces the size of this association, the association is not entirely explained by these [107,108].

Allergy to occupational allergens has been found to be

increased in smokers compared with non-smokers [109–111], though the same studies often showed no increase in the sensitivity to common inhaled allergens among smokers. In contrast, a number of studies have shown that the sensitivity to common allergens is reduced among smokers [42,104,107,108]. In two of these studies [107,108], the response to mite allergens was apparently dissimilar to that of the other common inhaled allergens including grass and cat. All these studies are cross-sectional and might be biased by the tendency of those who are sensitized to avoid smoking. However, evidence from the Tucson study suggests that this is not the explanation [28].

The effect of maternal smoking on sensitization is disputed. Magnusson reported an increase in cord IgE and subsequent infant allergy in the children of mothers who smoked during pregnancy. However subsequent investigators have generally not been able to replicate this [112].

Smoking causes a temporary increase in airway responsiveness [113], although smokers also develop a more persistent airway hyperresponsiveness [5,114,115]. This is associated with a fall in baseline airway function and does not reverse on quitting smoking [6], suggesting that it is secondary to structural damage to the lung. Patients with asthma who give up smoking experience a reduction of airway responsiveness [116], but there is little evidence that smokers are at any increased risk of developing asthma [117].

Since Colley [118] first drew attention to the effects of 'passive' smoking on the respiratory health of infants, a large body of literature has grown up to support his conclusions [119], although this effect is generally less marked after the first year of life [120]. Some studies have shown an increase in airway responsiveness in the children of mothers who smoke [121,122] but others have found either inconsistent [123,124] or negative [125–127] results. In Saskatchewan, non-allergic children and adolescents exposed to smoking had an increased prevalence of 'asthma' that was not found in the allergic children [128]. Evans and colleagues [129] found that asthmatic children from families that smoked were more likely to use emergency rooms, though this may have been due to unresolved confounding by other social factors. In contrast, Ehrlich and colleagues [127] found an increased prevalence of asthma in the children of mothers who smoked but were unable to show an increased risk of acute attacks of asthma.

## Air pollution

Air pollution is frequently cited as an important cause of asthma and its exacerbation. There is no good evidence that air pollution in general causes asthma, though it has been hypothesized that traffic pollution may be a cause of

the increased prevalence noted recently in the market economies. The pollution traditionally associated with cities, where coal burning was a major source of sulphur dioxide and particulates, has largely disappeared from the countries that have experienced the major increase in asthma prevalence.

Changes in symptoms and lung function have been noted in both normal and asthmatic populations in relation to increases in air pollution, although these have been for the most part relatively mild changes. Studies of mortality and admissions for asthma in relation to air pollution episodes have generally shown equally small and inconsistent effects. Several investigators have been surprised by such findings. During the famous London smog of December 1952 John Fry, a general practitioner in south London, reported that there was almost no effect of the smog on his young asthmatic patients [130]. In the air pollution episode that affected a large part of central Europe in 1985, admissions rose in affected areas compared with unaffected areas for stroke, ischaemic heart disease and chronic obstructive pulmonary disease but, if anything, fell for asthma [131]. These findings seem to bear out the observations of Henry Hyde Salter that 'it is, one may almost say, a *law* of asthma for it to be better in the air of great cities' [132].

On the other hand, there have been major [133] and some less extensive [134] episodes in which asthma has been reported to have been a problem, and the APHEA studies in Europe showed a modest increase in asthma admissions related to increases in nitrogen dioxide and, in children, with increases in sulphur dioxide levels [135].

One complicating factor in all of this is the role that might be played by allergen. The dramatic effects of exposure to allergen have already been described and the question arises whether allergen may play a role also in more normal circumstances. It is notable that the epidemics in Barcelona that were eventually shown to be due to the release of soybean allergen were at first attributed to oxides of nitrogen [136]. The reason for this is that the same weather conditions that lead to the build-up of one type of pollution may also lead to the build-up of another. The problem has been that there is no way of monitoring allergen, only a limited range of allergenic particles, such as pollens and molds, or specific allergens that have been identified and are under suspicion. However, the data from Barcelona suggest that low levels of allergen can contribute to asthma admissions without producing epidemics [137] and other allergens such as latex have been demonstrated in respirable particles from ambient air [138]. Such confounding could explain the relatively weak and inconsistent effects of air pollution on asthma.

## Infection and infestation

Frick [139,140] suggested that viruses could potentiate

sensitization to aeroallergens. Some bacterial antigens can act in the same way and pertussis vaccine can enhance IgE responses in animals [141], though natural pertussis infection does not lead to persistent respiratory disease [142,143].

As many as 70% of children respond to respiratory syncytial virus (RSV) with specific IgE, although those that have persistent anti-RSV IgE tend to have a family history or a personal history of wheeze [144]. This suggests that response with IgE may be normal but that persistence of the response is dependent on some other personal characteristic, possibly a genetic susceptibility. While it is true that children who develop RSV bronchiolitis are more likely to go on to develop episodic airways obstruction [145], it is not clear that this is cause and effect; it may simply be that those who are going to develop asthma and who become infected with RSV are more likely to have a severe episode of bronchiolitis. It has been shown, for instance, that children who are born with small airways are more likely to develop wheezing when they contract a lower respiratory tract infection [146]. The principal evidence against this interpretation in the case of RSV is the coincidence between the month of birth of those who develop asthma severe enough to be admitted to hospital and the month of birth of those who develop bronchiolitis [147]. It has also been suggested that persistent steroid-resistant asthma may be induced by chronic adenoviral infection [148].

On the other hand, there are alternative theories that suggest that early infection may suppress allergic responses and even the development of the atopic phenotype. In West Africa, a history of severe infection with measles was shown to be associated with a reduced prevalence of atopy, particularly sensitivity to mite allergen [149]. A strong response to tuberculin in Japanese school-children who had received bacille Calmette–Guérin (BCG) vaccine was also inversely related to atopy [150]. Serological evidence of infection by hepatitis A has also been shown to be inversely related to the prevalence of atopy in Italian military recruits [151]. All of these studies have been used to argue the case that early infection may affect the development of the immune response from one characterized by T lymphocytes producing interleukin (IL)-2, interferon  $\gamma$  and tumour necrosis factor to one characterized by T lymphocytes producing IL-4, IL-5, IL-6 and IL-10. At least in the second of these studies it is likely that those who respond to BCG with a tuberculin response are less likely to respond to allergen with an atopic response, rather than that BCG infection itself alters the immune response [150].

The simple view that any early infection reduces the risk of atopy is not well substantiated. Although Martinez and colleagues [152] have found that children experiencing non-wheezing lower respiratory tract infections in early life have a lower prevalence of atopy, Strachan and col-

leagues [63] found no association between early infection and subsequent atopy. Nor is there evidence of an inverse relationship between atopy and the common childhood infections [153].

There is much better evidence that acute viral infections of the respiratory tract, particularly rhinovirus and parainfluenza virus infections, cause acute exacerbations of asthma. Viruses cause exacerbations of asthma in both children [154] and adults [155] and infections are the commonest reported cause of exacerbations of asthma at all ages [27]. It seems likely that there is an interactive effect of viral infections and allergy in causing severe episodes of respiratory disease in children [156].

## Diet

Until the introduction of effective treatments for managing asthma, there was considerable interest in the effects of diet on the condition, and early in the twentieth century there were already hypotheses that food might induce asthma by anaphylaxis or by pharmacological means. The resulting fashion for restrictive diets was reversed in the middle of the century following increasing concern over the effects of these diets on nutrition and the introduction of double-blind food challenge as the criterion for assessing hypersensitivity to food. Although food sensitivity is common in children, and as many as 13% of adults complain of food-associated symptoms, current estimates of true food sensitivity in adults lie between 1 per 10000 and 2.3 per 1000 [157].

## Infant feeding

There is some evidence that allergy in early life may be reduced by breast-feeding and allergen avoidance. A randomized controlled trial of breast milk in premature neonates found less allergy in the treated children, but only among those who had a family history [158]. Zeiger and colleagues [159] also found a reduction of atopic disease in breast-fed babies where both mother and baby avoided allergen in the diet, but were unable to show a reduction in either rhinitis or asthma or in sensitization to inhalant allergens. Although Burr and colleagues [160] were able to show a reduction in wheezy illness early in life in those babies who had been breast-fed on any occasion, most studies show little difference in the incidence of asthma in those who were breast-fed and those who were not [161]. This is the conclusion from the two large British birth cohorts [162,163] and the Melbourne cohort in which the subjects with the longest history of breast-feeding had the worst asthma [164].

## Overall nutrition

There is little evidence on the effects of overall nutrition on

asthma, although there is some evidence that children with protein-calorie malnutrition are less likely to show skin sensitivity to common allergens [165]. At an ecological level, Keeley showed that the response to exercise in African children was related to body size, with the communities with smaller and lighter children having the least response to exercise. Such ecological data are hard to interpret, but Sommerville and colleagues [166] have also shown that children who are heavy for their height are more likely to have wheezy illnesses and in the Second National Health and Nutritional Examination Survey in the USA a two standard deviation increase in triceps skin-fold thickness increased the prevalence of frequent wheeze by 60% [167].

### Lipid

The Victorians believed in the efficacy of cod liver oil for asthma [168] and interest in this was revived by a corresponding interest in the role of lipid mediators in asthma. Clinical studies showed that fish oil in the diet could reduce the production of lipid mediators and blunt the late allergic response [169] but this had little influence on clinical asthma and aspirin-sensitive asthmatic patients deteriorated [170]. More recently interest has returned to this mechanism, with some epidemiological evidence that those who eat a diet rich in fish are less likely to have asthma [171]. However, others have been unable to demonstrate any difference in the  $\omega$ -3 fatty acid content of the diet of women who became asthmatic in middle life [172].

### Antioxidants

The lung has elaborate defences against oxidant damage and these are likely to be stressed in patients with asthma. Some of these defences are dietary in origin and Seaton has suggested that the increase in asthma may be due in part to a change in the diet with, in particular, a decline in the consumption of vitamin C. Trials of vitamin C in patients with asthma were first undertaken in the 1930s, with little success [173,174], and trials since that time have had mixed results. While neither Kreisman and colleagues [175] nor Malo and colleagues [176] were able to demonstrate any effect on either symptoms or hyperresponsiveness, others have reported reductions in the number and severity of attacks, the response to exercise and the response to methacholine. There are moreover several studies that have demonstrated lower levels of vitamin C in asthmatic patients [177–180] and those with hyperresponsiveness [181]. Low levels of vitamin C have also been associated with low lung function in men [182] and symptoms of chronic bronchitis [167].

In addition to the effects of vitamin C, there is suggestive evidence that vitamin E may also protect against the

onset of asthma in mid-life [172]. Selenium is a further micronutrient that has an important role in antioxidant activity in the lung. A number of studies have demonstrated a low level of selenium in patients with asthma [183–186]. One small randomized controlled trial has shown a clinical improvement in those taking selenium supplements but no change in lung function or airway reactivity [187].

### Electrolytes

Two electrolytes have received most attention with regard to their effects on asthma. Magnesium has been used for a long time as a bronchodilator [188], although it has disappointing results in acute severe asthma. A number of studies have shown that dietary magnesium is associated with lower prevalence of airway hyperresponsiveness in population surveys [181,189], though experimental studies have not suggested a strong effect on airway responsiveness [190]. Dietary sodium has been associated with increased bronchial responsiveness in one study [191], while other cross-sectional studies have shown weak or negative effects [192,193]. Experimental studies have suggested that a high sodium load does increase airway responsiveness in men [194,195] but not in women, and this is consistent with a finding that regions of England with high sales of table salt had an increased mortality from asthma for men and children but not for women [196]. The mechanism is unknown but it has been shown that serum from men with asthma increased sodium influx into donor cells and that this influx and dietary sodium were independently related to the airway responsiveness [197].

### Prognosis

#### Symptoms and lung function

A high proportion of children wheeze, though relatively few persist with severe respiratory problems. In the 1958 birth cohort, of all the children whose parents had reported wheeze in the first 7 years of life, only 50% were still wheezing at 7 years, 18% at 11 years and 10% at 16 years. At 23 years, this figure was still only 10% but by 33 the figure had risen again to 27% [43]. During childhood the reduction in symptoms with age is paralleled by a fall in airway responsiveness [198]. A relatively poor prognosis is associated with the presence of atopy and severity of disease, which is itself associated with atopy. Of those with persistent symptoms in childhood, relatively few are symptom-free in adult life [199].

A low lung function and bronchial responsiveness in childhood are predictive of low lung function and bronchial responsiveness in adult life [200]. Furthermore, those who have persistent wheeze during childhood and

are still wheezing in adulthood have low lung function that is not fully reversed by salbutamol. However, although symptomatic children have low lung function, the growth of their lung function with age is normal [201]. It seems likely therefore that asthma does not have an adverse effect on lung growth in childhood. In adulthood the effects of asthma on decline in lung function are unclear. Poor lung function is clearly associated with severe asthma [202] and is also associated with an increased mortality both in those with asthma [203] and others [204]. However, although two studies have reported a more rapid decline in lung function in patients with asthma [205,206], others have not [207] and Burrows and colleagues [208] found a normal rate of decline in lung function in those who had an unequivocal diagnosis of asthma with evidence of atopy and no history of smoking.

### Mortality

Follow-up of representative populations in the UK [209] and the USA [210] has shown an excess of mortality in those with diagnosed asthma. This excess increases with age and is negligible under the age of 45 years. Evidence from the life assurance companies also suggests that there is a small excess of mortality in those with a diagnosis of asthma, but this source also identifies a reduced mortality in those with other allergic diseases. This latter observation may explain why there is no excess of mortality in younger age groups although deaths from asthma do occur.

### Recording

Most studies of the validity of mortality statistics in asthma have studied the certificates and circumstances of death of those who have been certified as dying of asthma. These have generally concluded that, at least in younger subjects, the certificates are fairly accurate [211,212] though others have suggested that the certificates overestimate the number of deaths due to asthma [213]. For a clear view of accuracy, a study needs to assess both false-positive and false-negative rates. Where this has been done it has been found that the false-positive certificates are likely to balance or outweigh the false-negative certificates [214–216].

Vagueness in the definition of asthma and the presence of multiple pathology in older subjects inevitably leads to some uncertainty in ascribing any death to asthma in this age group. However, it also seems likely that there are more systematic biases in the variation in certification from country to country. Kelson and Heller [217] sent case histories to samples of doctors who had signed death certificates in eight European countries and asked them to complete death certificates for each of the cases. There was

considerable variation between countries and these differences related to the recorded mortality rates from asthma for the countries in the study [8].

### Trends

Overall mortality rates from asthma in England and Wales have not changed greatly over the course of the century. However this has not been consistent in all age groups. While mortality from asthma in the older age groups has declined throughout the century, that in adolescents and young adults has tended to rise [99]. In addition, there have been increases in mortality in the 1960s [218] and the 1980s [219].

### Overtreatment

Possibly because the early writers on asthma assumed that it was a largely benign condition that did not kill patients, much of what has been written on the subject since has related to iatrogenic causes of death. Early case reports concentrated on the dangers associated with respiratory depressants [220,221], while in more recent times the dangers of aspirin and other non-steroidal anti-inflammatory drugs have been emphasized. Of greater concern, however, has been the possibility that the drugs used to treat asthma might themselves be responsible for the deaths.

The first to suggest this were Benson and Perlman [222] who noticed that patients using epinephrine (adrenaline) sprays, mostly sold by door-to-door salesmen, had a seven-fold risk of death from asthma. The problem that was unresolved by this study was whether those taking the sprays had more severe disease. The hypothesis was revived in the 1960s when there was an increase in mortality from asthma in a number of countries that had licensed high-dose isoproterenol inhalers for the management of asthma. Early enquiries showed that a high proportion of the asthmatics who died were using these [223], while other studies showed a close association between the time course of the deaths and the use of these medications [218,224].

A further epidemic of deaths from asthma in New Zealand in the 1980s led to renewed interest in this hypothesis, in this case implicating the drug fenoterol. This was another potent bronchodilator prescribed in high doses and widely used in New Zealand. Case-control studies identified patients treated with fenoterol as being at increased risk, and the time course of the epidemic of deaths was interpreted as being compatible with fenoterol having been responsible. Despite this, a prospective study in Canada was unable to confirm the finding, though it showed that both salbutamol and fenoterol were prescribed in increasing amounts prior to the death of an asthmatic patient. The question of how far fenoterol was to

blame for the increase in asthma deaths in New Zealand in the 1970s and 1980s is still controversial. However, it is clear that there were less spectacular increases in deaths in other countries such as the USA at the same time where fenoterol was not licensed.

### Undertreatment

Another line of inquiry into asthma deaths has focused on undertreatment. Historically, much of the evidence for undertreatment being associated with death has come from uncontrolled enquiries into asthma deaths [225–229]. More recently, however, there has emerged more specific evidence that treatment with steroids may reduce mortality substantially [230,231]. Those treated with regular

inhaled steroids appear to have approximately one-third the risk of death of those who are not.

### Summary

Asthma is a disease that has become increasingly common over the last century. Although it is very variable in its severity, it is now a common cause of disability. The causes are still unknown. It has a genetic component although this cannot explain the increase in the disease or much of the variation in prevalence. It is associated with atopy but only a minority of atopic individuals are asthmatic. The major questions remain what circumstances lead to an increase in the disease and what factors lead to a deterioration in the condition.

# ASTHMA: CELLULAR AND HUMORAL MECHANISMS

CHRISTOPHER HASLETT

The cellular and mediator mechanisms of asthma must be considered in relation to the clinical definition and classification. The widespread acknowledgement that asthma is caused by a chronic inflammatory response in the airways has been arrived at as a result of information gained from histological studies in autopsy specimens (and more recently bronchoscopic bronchial biopsies in patients), the study of mediator and cellular interactions in allergen-challenged atopic patients and, to a lesser extent, the study of experimental animal models. In this chapter, the cellular and mediator mechanisms likely to underlie the asthmatic state and the effector mechanisms that may explain the pathological features are described.

## Clinical definition and classification

A full understanding of basic mechanisms must ultimately explain the clinical picture of airways obstruction that is variable (or reversible) as a result of therapy or spontaneously. It should also account for the propensity of asthmatic patients to show markedly heightened responses to direct bronchoconstrictor agents, or indirectly to triggers such as exercise and cold air. It is now widely considered that in many or most cases, the syndrome of asthma or the asthmatic state arises from a number of poorly understood inducing stimuli, such as allergens and chemicals, in a group of patients who are in some way genetically predisposed. The patient with asthma is 'primed' or at risk of severe bronchospasm if exposed to trigger factors, which may be specific allergens or non-specific trigger factors such as viruses or exposure to cold air (Fig. 33.1).

## Pathology

The macroscopic and histological appearances of the airways of patients dying from status asthmaticus show quite clearly that severe asthma involves much more than simple bronchoconstriction. Naked eye examination shows that many airways are blocked with thick, tenacious mucus [1].

Histological analysis reveals that airway narrowing is not just brought about by shortening of the airway musculature but also by inflammatory oedema of the whole airway, particularly the submucosal layer [2]. There is often marked thickening of the epithelial basement membrane and in many patients, particularly those with severe asthma, the bronchial epithelial lining is damaged, with evidence of epithelial injury, desquamation and even large areas of complete epithelial denudation and exposure of the epithelial basement membrane (see Fig. 34.6) [3,4]. In keeping with the excessive mucus production, there is marked hypertrophy and hyperplasia of submucous glands and goblet cell hyperplasia [5]. There is also evidence of smooth muscle cell hypertrophy and hyperplasia in the muscularis layer, and microvascular vasodilatation in the adventitial layer of the airway. Throughout the layers of the airway there is an intense inflammatory and immunological cellular infiltration, with large numbers of granulocytes (particularly eosinophils) in the submucosa and within the epithelial layer and mucous plugs [5,6], together with evidence of eosinophil degranulation and disgorgement of highly histotoxic products, e.g. major basic protein (MBP), on histochemical staining [7]. Elsewhere in the airway there are heavy infiltrations of chronic inflammatory mononuclear cells, including large numbers of T lymphocytes, particularly CD4<sup>+</sup> cells [8].

Although it may have been thought that these features were predominant only in the catastrophic forms of asthma, early studies of sputum, necropsy studies on patients dying from unrelated causes (e.g. road traffic accidents) and the application of bronchoscopic biopsy techniques in asthmatic patients have clearly demonstrated that many are also found in the background histological picture of asthma [9–14] and in atopic patients challenged experimentally with relevant antigens [15–17].

## Atopic asthma and allergen provocation

Atopic asthmatics constitute the larger subgroup of

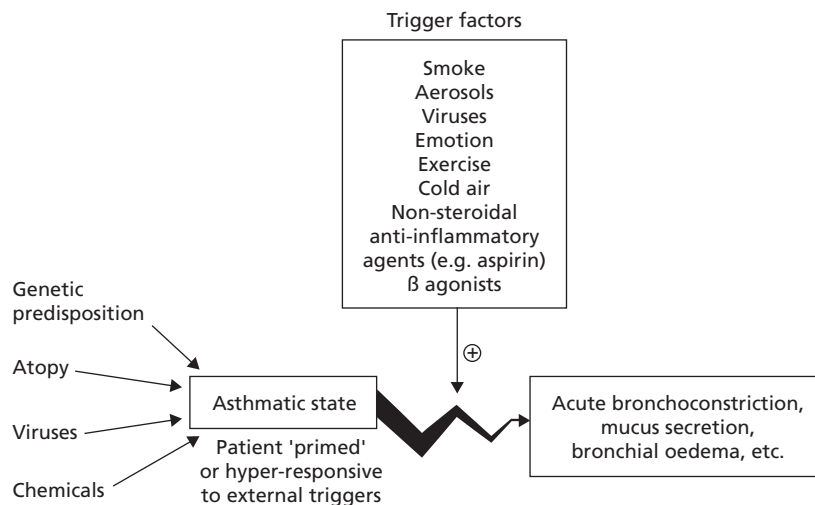

Fig. 33.1 The asthmatic state.

patients, and the study of their bronchial secretions (by bronchoalveolar lavage) and histology (by bronchial biopsy) at various times after deliberate antigen challenge has led to important insights into the mechanisms of asthma. While this experimental approach does not compare exactly with natural exposure to allergens, it has been extremely useful as a human model of asthma, providing much valuable information on the likely pathogenesis of allergic asthma and in the design and testing of new therapeutic agents. When the airways of most atopic asthmatic patients are challenged with specific allergen, the bronchial responses occur in two phases. The first rapid phase of bronchoconstriction (the early asthmatic response) reaches a peak within 20 min of challenge and recovers spontaneously within 60 min or so [18]. This response is thought to resemble a type I anaphylactic response, occurring as a result of IgE-triggered mast cell secretion of histamine and other rapidly acting bronchoconstrictor agents [19,20]. It can be prevented by prior treatment with the mast cell-stabilizing agent sodium cromoglicate (cromoglycate) and abrogated by  $\beta$  agonists [21]. This response is not significantly influenced by a single treatment with corticosteroids. The late asthmatic response occurs in around 50% of atopic individuals. It begins 4–6 h after challenge and persists for 12 h or more [18]. The mast cell is again likely to play an important role in this phase of bronchoconstriction since it is also attenuated by sodium cromoglycate. However, cytological and histological studies also show submucosal oedema, vascular dilatation and a complex cellular infiltration of granulocytes (especially eosinophils) and CD4<sup>+</sup> T lymphocytes, which are linked to a Th2-type cytokine secretion profile including interleukin (IL)-3, IL-4 and IL-5 [22].

The distinction between the early and late phases, which is a useful simplification in research, is of little value in the clinical context as most cases of severe asthma are likely to involve a multiplicity of mechanisms combining

elements of both the acute and chronic inflammatory responses.

## The cells

In this section the role of important cell types in asthma is considered. Although it is a somewhat artificial separation they can be segregated into the following groups.

1 Constitutive or resident cells of the airway, including tissue macrophages, dendritic cells and mast cells. These resident airway cells generally function to initiate the inflammatory and immune responses, although the mast cell clearly has many important effector functions in asthma.

2 Inflammatory/immune blood-borne cells, including the granulocytes and lymphocytes recruited to the inflamed asthmatic airway and which are likely to play additional important pathogenetic roles.

## Resident cells

### Cells of the monocyte/macrophage series and dendritic cells

By far the most numerous cell in the airway is the resident tissue macrophage. Under homeostatic conditions in healthy airways this population of cells is continuously replenished by bone marrow-derived, blood-borne monocytes. The resident macrophage expresses the low-affinity IgE receptor and can secrete a wide range of proinflammatory cytokines and chemokines [23]. These cells perform a key sensing and regulatory function in the inflammatory response, particularly in its initiation phase, although their precise contribution to the pathogenesis of asthma is uncertain. They rapidly secrete cytokines (Table 33.1) such as IL-1 and tumour necrosis factor (TNF)- $\alpha$  that act on microvascular endothelial cells [24,25], causing them to express

**Table 33.1** Some important cytokines: their source and major function.

Cytokine	Source	Functions
IL-1	Macrophages and other cell types	Activation of endothelial cells and macrophages, fever, T cell co-stimulation
IL-2	T cells	T-cell growth factor, NK cell activation
IL-3	Bone marrow stromal cells, T cells	Growth factor for neutrophils, eosinophils, mast cells
IL-4	T cells (Th2) and mast cells	B-cell IgE isotype switching, growth factor for B cells and T cells
IL-5	T cells (Th2) and mast cells	Eosinophil differentiation, recruitment activation and inhibition of apoptosis. Growth factor for B cells
IL-6	Macrophages, T cells and other cells	Acute-phase protein production, B and T cell growth and differentiation
IL-7	Bone marrow stromal cells	Growth factor for pre-B and T cells
IL-8	Reclassified as C-X-C chemokine	
IL-9	T cells	Mast cell activation
IL-10	B cells and macrophages	Inhibits macrophage function
IL-11	Bone marrow stromal cells	Growth factor for haematopoietic stem cells
IL-12	Macrophages and B cells	Promotes differentiation of Th1 cells, activates NK cells
IL-13	T cells (Th2)	B-cell IgE isotype switch, B-cell growth factor
IL-14	T cells	Development of memory B cells
IL-15	Macrophages and other cell types	Growth factor for T cells
IL-16	T cells (CD8 <sup>+</sup> )	Chemoattractant for CD4 <sup>+</sup> T cells and macrophages
TNF- $\alpha$	Macrophages, monocytes and T cells	Activates endothelial cells, stimulates release of IL-8 and other chemokines from resident cells
TNF- $\beta$	T and B cells	Activates endothelial cells, CD8 <sup>+</sup> -mediated cytotoxicity
IFN- $\alpha$	Macrophages, T and B cells	Antiviral activity, increased MHC class I expression
IFN- $\beta$	Fibroblasts and other cells	Antiviral activity, increased MHC class I expression
IFN- $\gamma$	Macrophages, T cells and other cells	Activates macrophages and CD <sup>+</sup> T cells, antiviral activity
TGF- $\beta$	Macrophages, monocytes and T cells	Inhibits macrophage function, promotes fibrosis and wound repair
GM-CSF	Monocytes, macrophages and T cells	Growth factor for myeloid cells, primes macrophages, primes and inhibits apoptosis in neutrophils and eosinophils
PDGF	Macrophages and platelets	Growth factor for fibroblasts, repair, fibrosis
FGF	Macrophages	Growth factor for fibroblasts, repair, fibrosis

FGF, fibroblast growth factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; IL, interleukin; NK, natural killer; PDGF, platelet-derived growth factor; TGF, transforming growth factor; TNF, tumour necrosis factor.

the adhesion molecules (Table 33.2) required for leucocyte trapping and emigration. They also secrete certain chemokines such as IL-8 and gro- $\alpha$  that are specifically chemotactic for neutrophil granulocytes [26,27], whereas others such as RANTES and monocyte chemoattractant protein-1 (MCP-1) attract eosinophils and monocytes [28,29]. Macrophage-derived IL-1 and TNF- $\alpha$  can also act on other resident tissue cells, for example fibroblasts and epithelial cells, inducing them to secrete IL-8 and other chemokines [30,31] and thus amplifying the inflammatory response.

In the development of an acute inflammatory response, the initial emigration of granulocytes from blood into tissues is followed by a wave of monocyte emigration. These cells rapidly mature into inflammatory macrophages, which can also secrete cytokines and chemokines and amplify the inflammatory response. However, these cells possess much more effective mechanisms for the secretion of enzymes and reactive oxygen species than do resident macrophages and may thus play an important role in the effector limb of asthma. Macrophages also secrete the cyclooxygenase products thromboxane (TX) $B_2$  and prostaglandin (PG) $E_2$ , the 5-lipoxygenase product leukotriene (LT) $D_4$  and platelet-activating factor (PAF), which are capable of inducing many of the features of

asthma [9,32,33]. Cells of the monocyte/macrophage series are also able to influence T-lymphocyte function through the secretion of cytokines, and while resident macrophages are poor presenters of antigen, monocytes and immature inflammatory macrophages are more effective. Although there is little direct evidence for the macrophage in the pathogenesis of asthma *in vivo*, the circumstantial evidence is impressive and it is hard to believe that it does not play an important role.

The lung dendritic cell is likely to play the major role in antigen presentation to T lymphocytes. These cells are prominent in the submucosal layer of the airway, particularly beneath the epithelial lining.

### Mast cells

These highly granular tissue cells have long been implicated in the pathogenesis of allergic conditions, particularly asthma. Ultrastructural examination (Fig. 33.2) reveals large numbers of cytoplasmic granules with a characteristic morphology. Reports vary as to whether there are increased numbers of mast cells in the asthmatic airway, although most ultrastructural studies show that those present display an activated, degranulated

appearance. Being the most important cellular source of histamine, it has been clear for some time that the mast cell plays a key role in the effector limb of asthma. In addition to secreting preformed mediators such as histamine, mast cells can also synthesize other mediators in the cyclooxygenase pathway, especially PGD<sub>2</sub>, and 5-lipoxygenase arachidonic acid pathways that exert rapid effects on the airway [34–37]. Another important granule component is tryptase, which besides exerting a number of effects on the airway also activates the kinin cascade. Mast cells may be triggered by direct binding of IgE via their high-affinity surface receptors or by cross-linking of these receptors but can also be triggered indirectly by cold air or by changes in tonicity of the fluids in the airways [38,39]. Recent studies suggest that the mast cell, like the resident macrophage, is an important regulatory cell: when atopic airways are challenged with specific allergen, airway mast cells rapidly generate mRNA for IL-3, IL-4 and IL-5, the Th2-type cytokines [40,41]. This cell is clearly a major player in the pathogenesis of asthma (Figs 33.2 and 33.4).

### Basophils

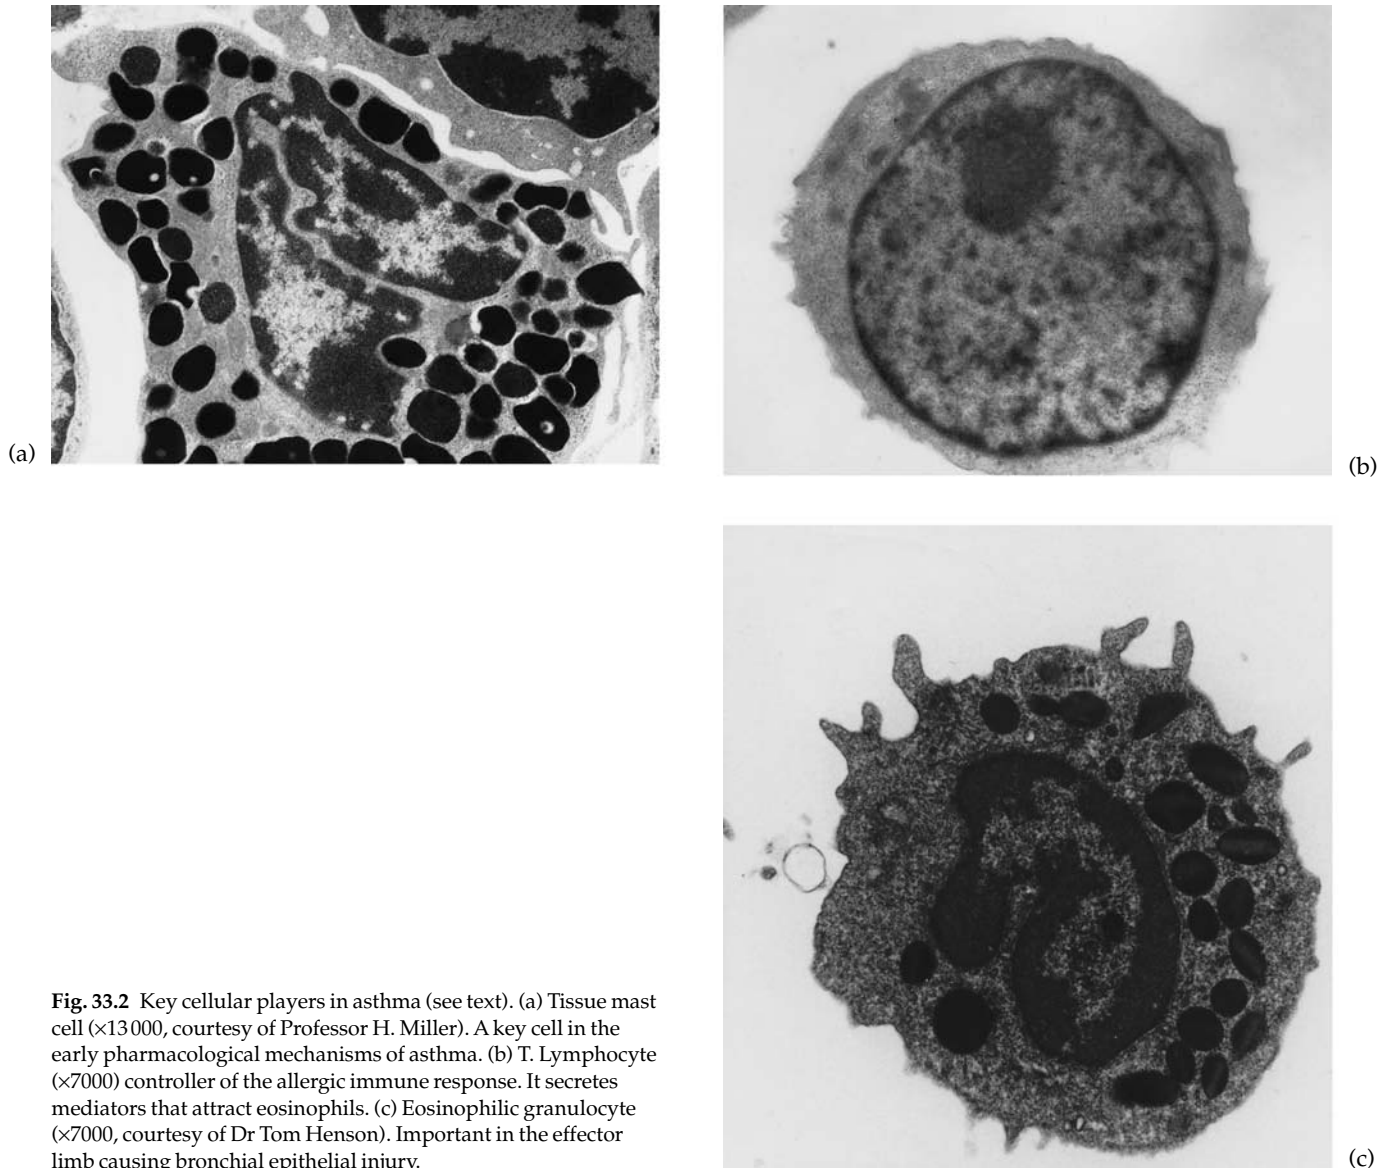

The role of these cells in asthma has been difficult to establish, partly because they lack specific surface markers that would aid histological identification and purification for detailed *in vitro* study. While there is uncertainty about whether increased numbers are present in asthmatic airways, they can be found in the blood during the asthmatic response [42,43]. Like mast cells, basophils possess

the high-affinity IgE receptor and when triggered can secrete histamine and a wide range of other mediators relevant to the pathogenesis of asthma [44–48]. Unlike mast cells they can also be stimulated by the cytokines IL-1 and IL-3 and by the chemokines IL-8 and RANTES.

### Circulating leucocytes

#### Eosinophils

Eosinophils are bone marrow-derived, blood-borne polymorphonuclear leucocytes, the cytoplasmic granules of which stain a deep pink with haematoxylin/eosin; hence the name and their distinction from the neutrophil granulocyte. Ultrastructural examination (see Fig. 33.2) reveals large angular granules possessing the dark, crystalline core that characterizes this cell type. Eosinophil granules contain not only many of the potentially histotoxic agents found in the neutrophil but also a number of eosinophil-specific agents, including major basic protein (MBP) and eosinophil cationic protein (ECP) that help identify the cell and provide evidence of its secretory activity *in situ* [7,49,50]. Atopic asthmatics have long been recognized to display high circulating levels of eosinophils in the blood and large numbers of eosinophils and Charcot–Leyden crystals (lyssolecithin from degraded eosinophils) in their sputum [51,52]. Histological studies of severe asthmatics reveal heavy infiltrations of the airways with eosinophils [6,53,54], many of which show evidence of degranulation on electron microscopy, together with evidence of dis-

gorged MBP and eosinophil peroxidase (EPO) in tissues [7]. These cationic products are highly toxic to epithelial cells *in vitro*, and eosinophils are widely considered to be responsible for much of the epithelial damage described in cases of severe asthma. Eosinophils possess functional low-affinity IgE receptors and can synthesize PAF and other important lipid mediators [55–65]. They can also secrete a variety of cytokines, including IL-4 that is so important in IgE secretion [66,67], and their reputation as a centrally important cell in the pathogenesis of asthma seems fully justified. Airway challenge of atopic patients with specific allergen results in eosinophil accumulation in the airways and bronchoalveolar lavage fluid, together with evidence of extracellular secretion of ECP and MBP. The characteristic eosinophil accumulation in the tissues in an allergic response is probably brought about by the local

secretion of specific chemokines (MCP-1 and RANTES) and cytokines (IL-5) that attract eosinophils, together with the expression of specific components of the adhesive molecule repertoire that trap them in local microvessels prior to their directed emigration. CD4<sup>+</sup> T cells and mast cells are probably responsible for most of the IL-5, granulocyte-macrophage colony-stimulating factor (GM-CSF) and IL-3 necessary for eosinophil production, recruitment and activation. Extravasated eosinophils are much longer-lived in tissues than are neutrophils, and cytokines such as IL-5 and GM-CSF that are important in the 'supply side' of eosinophils also have major effects in prolonging the functional longevity of these cells in tissues by exerting major inhibitory effects on eosinophil apoptosis, the process of natural cell death that controls the ultimate removal of extravasated granulocytes [68].

### Neutrophils (neutrophilic polymorphonuclear leucocytes)

The importance of these cells in human asthma is uncertain at present. In a number of experimental animal models of asthma there is a relationship between neutrophil influx and airway hyperresponsiveness, and the *Alternaria*-rabbit model appears to be neutrophil-dependent [69]. In equine 'heaves', a syndrome very like asthma that is due to exposure to allergens in mouldy hay, the disease is associated with neutrophil, not eosinophil, accumulation in the airways. However, in established human asthma, eosinophils rather than neutrophils are usually the dominant granulocyte in histological sections of the airway, although neutrophils are certainly present in significant numbers in most cases. In dynamic studies of allergen-challenged atopic patients, a wave of neutrophil migration precedes eosinophil migration. The neutrophil contains an enormous armamentarium of preformed agents in its granules (see Chapter 27) and is able to rapidly synthesize a range of agents, including PAF and cyclooxygenase products that are important in the effector limb of asthma pathogenesis. It is perhaps also worth considering that because the neutrophil lives for a much shorter time in tissues than do the eosinophil, lymphocyte and macrophage, the comparative paucity of neutrophils on histological sections could in fact represent a major tissue throughput and the neutrophil may play a more important role than has hitherto been thought.

### Lymphocytes

Lymphocytes are blood-borne leucocytes responsible for the classical immune response. They can also be regarded as tissue cells since, in the process of lymphocyte recirculation, they pass through the high endothelial venules of organs including the lung, transit the tissues and return to the bloodstream via the lymphatics. The expression of clonally distributed specific receptors for antigen is characteristic of both B and T lymphocytes, although the function of B lymphocytes is generally restricted to immunoglobulin synthesis and, in the lymph nodes, antigen presentation. T cells can be separated broadly into helper or regulatory (CD4<sup>+</sup>) cells and effector/cytotoxic (CD8<sup>+</sup>) cells based on their surface expression of CD4 or CD8 coreceptors. The important role of allergen-specific B lymphocytes in synthesizing IgE has long been recognized as a key mechanism in allergic asthma, although it is now clear that the T cell also plays a vital role in this response by acting as a helper cell and by secreting IL-4, which is responsible for switching B-cell immunoglobulin secretion from IgG to IgE.

However, it is now becoming apparent that CD4<sup>+</sup> T cells may play a number of other important roles: they are the only cells that can recognize and directly respond to

processed antigen on the surface of antigen-presenting cells (APC) and they are likely to represent the major airway tissue source of IL-5, GM-CSF and IL-3, which promote eosinophil recruitment, activation and longevity. In mice, antigen-activated CD4<sup>+</sup> T-cell clones can be divided broadly into two functional phenotypes [70,71]:

1 Th1: secretes IL-2, interferon (IFN)- $\gamma$  and TNF- $\alpha$  (*not* IL-4, IL-5, IL-6);

2 Th2: secretes IL-4, IL-5 and IL-6 (*not* IL-2, IFN- $\gamma$ , TNF- $\alpha$ ).

However, both types of cell secrete IL-3 and GM-CSF. It is not yet certain how directly applicable this subdivision is to humans, but it is clear that Th1 and Th2 patterns of cytokines may be dominant in different circumstances. A Th2 type of response would favour IgE synthesis (which is also inhibited by IFN- $\gamma$ ) and activation of mast cells and eosinophils, and there is preliminary evidence for this pattern of response in human asthma [72–75]. Bronchoalveolar lavage fluid from asthmatics contains increased concentrations of Th2 cytokines and the mononuclear cells from bronchoalveolar lavage fluid contain mRNA for IL-4, IL-5 and GM-CSF [76–78]. However the exact role of CD4<sup>+</sup> cells and possible regulatory role of CD8<sup>+</sup> cells require further clarification.

### Mediators

Hundreds of mediators have been implicated in the inflammatory and immunological processes that contribute to the pathogenesis of asthma, and it is difficult to know how best to categorize them, whether as biochemical groupings or under headings relating to their biological effects. One of the problems with the latter approach is that single mediators may possess a number of very different actions. Furthermore, for a single key function there are usually many different mediators, often from different biochemical cascades, that exert the same action. For example, there are a large number of agents that are chemotactic for neutrophil granulocytes, such as C5a in the complement cascade, LTB<sub>4</sub> in the prostanoid cascade and a variety of chemokines from the C-X-C subclass including IL-8, ENA-78 and gro- $\alpha$  (see Table 33.3). There are numerous examples of this type of redundancy, which probably evolved as an important part of the inflammatory and immune responses against microorganisms, for example should a bacterium develop an escape mechanism against a particular mediator, then there are a number of different back-up mediators to perform that action. Thus the mediators to be described should perhaps be considered as a network or web rather than as a series of pathways. Rather like a spider's web, if one strand is lacking this does not necessarily impair its overall integrity. This remarkable redundancy is undoubtedly of enormous value in antimicrobial host defence. However, when this same concept is considered from the perspective of designing effective mechanism-based therapy in inflammatory and immuno-

logical diseases such as asthma, where these complex networks are part of the disease pathogenesis, the prospects are indeed daunting. Although, intuitively, it would seem futile in established inflammatory/immunological diseases to adopt a single mediator strategy, there have indeed been attempts to do just this. To exemplify this problem, PAF can provoke virtually all the features of asthma (see below), yet when an extremely effective PAF antagonist (WEB2086), which blocks almost all its effects in model systems, was assessed in human asthma it was found to have no beneficial effects [79]. Glucocorticoids are likely to be effective in most cases of asthma because they have multiple actions at different points in the cellular and mediator events, yet unfortunately they also cause adverse effects. It seems likely that unless we are fortunate to identify key anchor strands of the spider's web of mediators, therapeutic strategies will need to be directed at more than one mediator or mechanism.

In this section the important mediators are described under the headings histamine, kinins, lipid mediators, cytokines and chemokines. The mechanisms whereby these agents might cooperate in the integrated cellular and mediator responses that characterize the asthmatic state are then considered.

### Histamine

The main source of histamine is the mucosal mast cell, although eosinophils may also contribute. Via the airway H<sub>1</sub> receptors, histamine causes rapid bronchoconstriction and induces dilatation and leakage of microvessels, which results in airway oedema and further narrowing of the bronchial lumen [80,81]. Histamine is thought to stimulate secretion of mucus in human airways via the H<sub>2</sub> receptor [82]. While it is likely to be an important mediator in all stages of asthma and particularly the early response, anti-histamines have proved disappointing in the treatment of human asthma, perhaps because of the redundancy factor

since prostanoids, leukotrienes and PAF can mimic most of its actions.

### Kinins

Bradykinin is detected in the bronchoalveolar lavage fluid of atopic patients after allergen challenge of the airways [83]. It acts as a potent constrictor of human airways *in vivo* [84], perhaps acting by indirect mechanisms such as the release of sensory neuropeptides and lipid mediators. Bradykinin is probably generated from preformed kininogens in plasma as a result of the action of kallikrein and mast cell tryptase. In addition to its action on smooth muscle and airway sensory nerves, it is a potent vasodilator and inducer of microvascular leakage and airway mucous secretion [85,86].

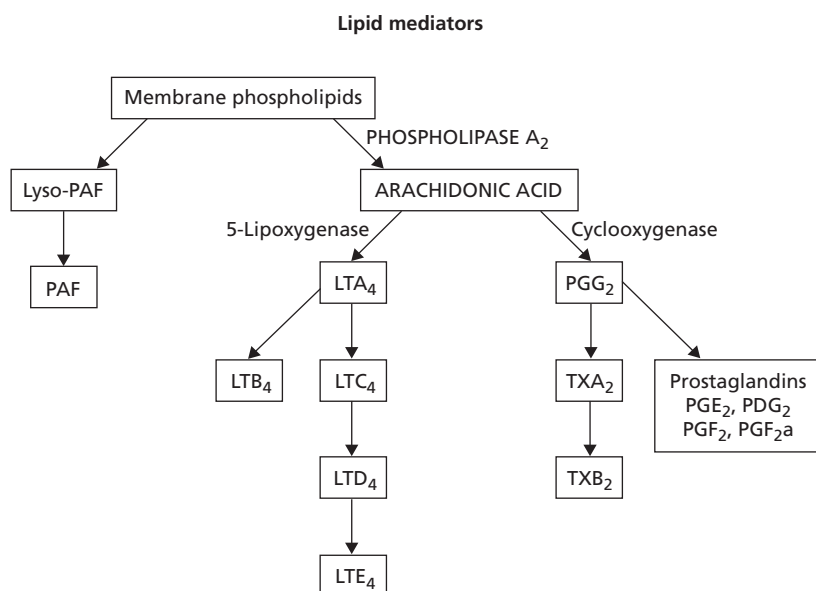

### Lipid mediators (Fig. 33.3)

#### Cyclooxygenase products

A wide range of inflammatory cells are able to synthesize the cyclooxygenase products (or prostanoids, i.e. prostaglandins and thromboxane) from membrane phospholipids; certainly macrophages and granulocytes are potent in this regard. Recent research has identified two forms of cyclooxygenase: COX1, a constitutive form present in unstimulated cells; and COX2, a form induced by TNF- $\alpha$  and other proinflammatory cytokines [87]. Unlike COX1, COX2 is inhibited by corticosteroids [87] and is likely to be responsible for the increased level of prostanoids found in the airways of asthmatic patients and atopic patients challenged with allergens [88,89]. PGD<sub>2</sub> and PGE<sub>2</sub> cause constriction of the airways by activating thromboxane TP<sub>1</sub> receptors, as do TXA<sub>2</sub> and its more stable metabolite TXB<sub>2</sub>. PGD<sub>2</sub> also primes or enhances the airway bronchoconstrictor response to histamine in asthmatic patients. Other prostanoids, including PGE<sub>2</sub> and PGI<sub>2</sub> (prostacyclin), may exert bronchodilator effects. The prostanoid family is likely to contribute to the bronchoconstrictor effect *in vivo*, as do many other redundant mediators, although potent cyclooxygenase inhibitors alone do not exert major beneficial effects on asthma *in vivo* [90].

### Leukotrienes

Activation of 5-lipoxygenase, particularly in macrophages, mast cells and granulocytes, results in the synthesis of LTB<sub>4</sub>, LTC<sub>4</sub>, LTD<sub>4</sub> and LTE<sub>4</sub>. Raised levels of these agents are found in bronchoalveolar lavage fluid after allergen challenge of atopic subjects [89,91]. LTB<sub>4</sub> is a potent neutrophil chemoattractant that has little effect on eosinophils and its role in asthma is uncertain. The sulphidopeptide leukotrienes (LTC<sub>4</sub>, LTD<sub>4</sub> and LTE<sub>4</sub>) are potent

**Fig. 33.3** Lipid mediators derived from membrane phospholipids that have a role in the inflammatory processes involved in asthma.

bronchoconstrictors and can induce bronchial hyperresponsiveness [92,93]. They can also exert potent effects on airway microvascular leakage and airway mucous secretion. It is possible that these agents may play a centrally important role in asthma and new 5-lipoxygenase inhibitors are being developed commercially, particularly directed against 5-lipoxygenase-activating protein (FLAP) [94]. Preliminary studies with LTD<sub>4</sub> antagonists show effectiveness against exercise- and aspirin-induced asthma.

#### Platelet-activating factor

This lipid mediator is synthesized by inflammatory macrophages and granulocytes. It was originally discovered through its action on platelets [95], although it has now become clear that it can mimic many of the features of asthma, including; bronchoconstriction and mucous secretion [93,96,97], and is a potent inducer of microvascular leakage [98]. It has also been found to exert important influences on inflammatory cells, including eosinophil recruitment, endothelial activation and eosinophil degranulation [99–102]. While it is likely that PAF makes important contributions to the mediator network in asthma, it does not seem to have a unique role because the powerful PAF antagonists (e.g. WEB2086) that block the effects of PAF *in vitro* and *in vivo* [103,104] are of little benefit in human asthma [79].

#### Cytokines and growth factors

The cytokines are a family of peptides secreted by inflammatory cells (and also some resident tissue cells) that cooperate to orchestrate the initiation, amplification and,

finally, cessation of the inflammatory and immune responses, plus the regulation of repair responses required to restore tissue integrity. The family now exceeds 50 members (see Table 33.1 for some of the more important ones), which are involved in a complex interplay with each other and with a variety of cells types in the regulation of these important tissue responses. Full understanding of the roles of the cytokine network has been hindered not only by the discovery of new family members almost weekly but also by the facts that (i) there is marked redundancy in many of the mechanisms (a variety of cytokines may exert the same action), (ii) the same cytokine may have multiple effects including different effects on different cells and (iii) some cytokines may require prior interaction with other cytokines before their own effects are revealed.

#### Interleukin 1

IL-1 has important direct actions on microvascular endothelial cells, activating them and upregulating their expression of adhesion molecules necessary for leucocyte trapping and emigration. It exerts important secondary effects by stimulating resident cells, such as fibroblasts and airway epithelial cells, to secrete IL-8 and GM-CSF [105,106]. Thus it is considered to be a key mediator in the control of the early-release mediators involved in the initiation of the inflammatory response, although it is not specific to the allergic response seen in asthma.

#### Tumour necrosis factor $\alpha$

There is much evidence for the release of this peptide and expression of the TNF- $\alpha$  gene in asthmatic tissues and in

allergen-provoked atopic patients [107,108]. It is secreted by macrophages and other inflammatory cells and also by bronchial epithelial cells. Like IL-1, it is likely to play an important role in the initiation of inflammation because it is a potent inducer of GM-CSF and IL-8 secretion by epithelial cells and fibroblasts and it activates microvascular endothelial cells to express intercellular adhesion molecule (ICAM)-1 and vascular cell adhesion molecule (VCAM)-1 [105,106,109,110].

### **Interleukin 3**

IL-3 is centrally important in haematopoiesis, particularly the growth and differentiation of neutrophil and eosinophil granulocytes, mast cells and basophils. At the inflamed site it is likely to promote eosinophil survival.

### **Interleukin 4**

Like IL-3, IL-4 is one of the Th2 group of cytokines produced by a subpopulation of CD4<sup>+</sup> T lymphocytes, although it can also be produced by mast cells in asthmatic patients [40]. Together with CD40L it is likely to play a critical role in switching B-lymphocyte immunoglobulin secretion from IgG to IgE [111]. It may also be important in inducing the expression of endothelial adhesion molecules (e.g. VCAM-1) that are important in monocyte and eosinophil emigration [112].

### **Interleukin 5**

IL-5 is produced by the Th2 subpopulation of CD4<sup>+</sup> lymphocytes and can also be secreted by mast cells. This cytokine is likely to be centrally important in asthma because of its major effects on various aspects of eosinophil function. It is necessary for the final differentiation of eosinophils in the bone marrow, their recruitment to the inflamed site, their activation [113] and, by inhibiting their inherent rate of apoptosis, is likely to exert important inflammatory amplification effects by prolonging their tissue longevity [68]. Raised levels of IL-5 have been found in the bronchoalveolar lavage fluid of asthmatic patients and atopic patients who have been challenged with allergens [114,115].

### **Granulocyte-macrophage colony-stimulating factor**

GM-CSF is produced by macrophages, granulocytes, lymphocytes and airway epithelial cells. It is important in the haematopoiesis of inflammatory cells, in priming macrophages, neutrophils and eosinophils for subsequent secretory responses and, by inhibiting apoptosis, in prolonging the functional lifespan of neutrophils and eosinophils. Once again, there is evidence for the expression and secretion of this important cytokine in asthma

and in allergen-induced bronchoconstriction in atopic patients.

### **Growth factors**

Attention has recently been drawn to the possible importance of thickening of the subepithelial basement membrane and the subepithelial fibrosis that has been observed in necropsy studies of asthmatic patients. Platelet-derived growth factor (PDGF), which in spite of its name is mostly derived from macrophages, exerts potent effects on fibroblast functions, including proliferation and collagen synthesis. Transforming growth factor  $\beta$  (TGF- $\beta$ ) and fibroblast growth factor (FGF) also stimulate fibroblast replication and collagen secretion. These cytokine growth factors may also promote smooth muscle proliferation and vascular remodelling in the chronic asthmatic airway.

Most cytokines so far discovered exert proinflammatory or profibrotic effects, yet in the healthy individual the beneficial inflammatory response to injury or infection is exquisitely controlled, with minimal damage to host tissues, prompt resolution and a fibroproliferative response (see Chapter 27) just sufficient to complete the minor repairs necessary to restore tissue integrity. It is possible that this tight regulation is achieved at the level of synthesis and secretion, although analogies in other cascades such as blood coagulation suggest that there are likely to be numerous inhibitory cytokines or partner molecules that keep cytokine responses in check. IL-12 exerts a number of inhibitory influences, particularly on macrophages, and the soluble form of the IL-1 receptor inhibits several early events in the initiation of inflammation; there are probably many more inhibitory cytokines to be discovered, some of which may yet be of therapeutic value.

### **Chemokines**

The comparatively recent discovery of this family of small peptides, many of which exert powerful and specific chemoattractant influences, has generated much interest. Until now there has been no really plausible explanation for the attraction of specific cell types at different stages of the inflammatory response and in different types of inflammation. Furthermore, the molecular characterization of specific chemokine receptors may lead to incisive therapeutic approaches in allergic inflammation. This family of mediators has been broadly divided into the C-X-C subgroup, in which the cysteine residues of the peptide are separated by an interposed amino acid, and the C-C subgroup where this is not the case (Table 33.3). In humans, the genes encoding the C-X-C group are located on chromosome 4 and those encoding the C-C group on chromosome 17. The C-X-C group contains the neutrophil

chemoattractants IL-8, neutrophil attractant protein (NAP)-2, gro- $\alpha$  and ENA-78. Platelet factor 4 is closely related molecularly but is not a chemoattractant. Lung macrophages are extremely potent producers of IL-8, which was originally classified as a cytokine but molecular characterization resulted in its reclassification as a chemokine. It is specifically chemotactic for neutrophils, although it is thought that in the presence of IL-4 it may also attract eosinophils. It also has important but poorly understood roles in neovascularization. In contrast, the C-C chemokine RANTES is a potent and specific chemoattractant for eosinophils [116,117], whereas its close relative macrophage-inhibitory protein-1 $\alpha$  (MIP-1 $\alpha$ ) is involved in monocyte and eosinophil chemoattraction.

### Orchestration of cellular and mediator events in the pathogenesis of asthma

As mentioned above, most asthma attacks in human disease probably involve elements of both the early and late responses observed when atopic individuals are exposed to airway-delivered specific allergens. Nevertheless, as a simplification of the very complex events *in vivo* it is helpful to consider each separately.

#### Early asthmatic response

In the sensitized individual, mast cells and perhaps also basophils are triggered by IgE, which binds via the high-affinity IgE receptor (Fc $\epsilon$ R1), causing prompt degranulation and secretion of preformed granule contents including histamine and tryptase (Fig. 33.4). Histamine causes rapid airway responses, including bronchoconstriction, vasodilatation/oedema and mucous secretion. Mast cell tryptase exerts direct actions on the airway but also activates the kinin system to generate bradykinin, a

powerful bronchoconstrictor. Activated mast cells also synthesize potent vasoactive and bronchoconstrictor agents, including PGD<sub>2</sub> and LTC<sub>4</sub>/LTD<sub>4</sub>/LDE<sub>4</sub>. The IgE that triggers mast cells is generated by T lymphocytes that have been activated by processed antigen on the surface of antigen presenting cells (APCs). Mast cells can also be triggered by cold air or by changes in the osmolality of the local tissue fluids. In the complex inflammatory picture of the chronic asthmatic airway, other cells including macrophages and granulocytes that display the low-affinity IgE receptor may also contribute to the synthesis and secretion of important vasoactive and bronchoconstrictor agents, including leukotrienes, prostanoids and PAF.

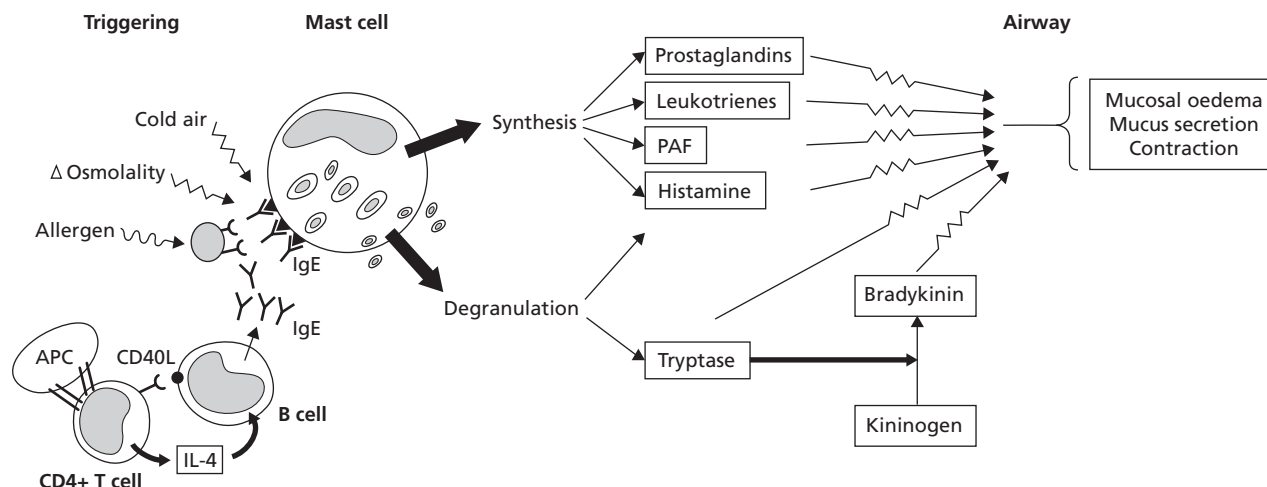

#### Late asthmatic response

Most asthmatic attacks in patients probably include elements of the mechanisms involved in the early asthmatic response but also involve major contributions from inflammatory cells (macrophages, neutrophils, eosinophils) and immune cells (lymphocytes), which have more complex, more prolonged and perhaps more damaging effects. The likely cellular events that follow the acute events described above when a sensitized individual is exposed to specific antigens are considered now. The discussion is divided into the cell recruitment phase and the effector mechanism phase, where products of inflammatory cells are likely to cause the histological features seen in severe asthma. However, while useful as a framework for understanding, the distinction is again somewhat artificial because in asthmatic patients acute and chronic inflammatory cells are often already present in airway tissues and because some damaging mechanisms are likely to have been initiated before cellular recruitment is complete.

#### Cell recruitment

Neutrophils are the first cells to arrive in the challenged

Fig. 33.4 Summary of the acute asthmatic response.

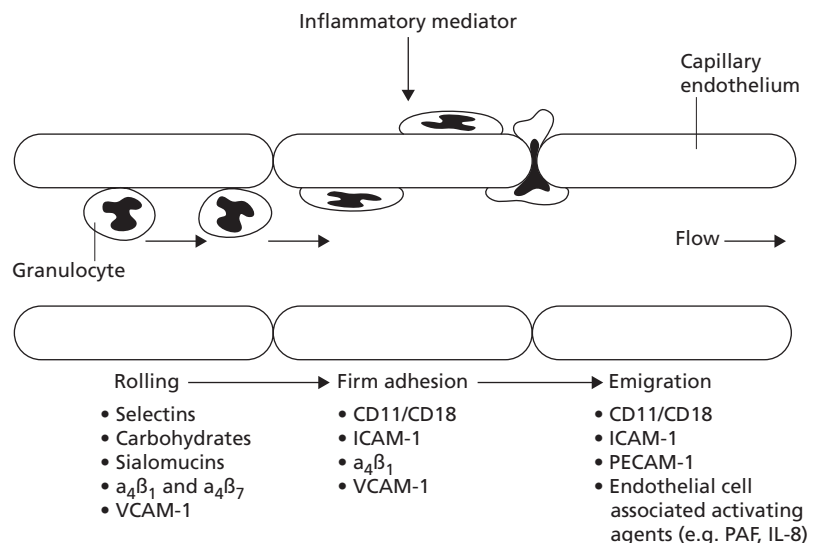

airways, followed by eosinophils and monocytes, which mature into inflammatory macrophages. The attraction of specific inflammatory cells is mediated by chemotactic factors. For the neutrophil, these would include the complement product C5a, LTB<sub>4</sub> and a number of chemotactic chemokines in the C-X-C group. IL-8 is perhaps the most relevant and powerful neutrophil chemokine in the lung. Eosinophils are attracted by a number of mechanisms, perhaps by the specifically eosinophilic chemoattractant peptide RANTES and a new member of the family the eosinophil-specific eotaxin [116–118]. Monocytes can be attracted by a number of chemokines in the C-C group. The selective emigration of neutrophils, eosinophils and monocytes is mediated initially by a trapping phase in the local microvessels followed by transmigration of the endothelial cell layer in the microvessels within the airway. This is a multistep process, the adhesion component occurring in at least two phases that utilize different components of the adhesion molecule repertoire (see Table 33.2). The early arrest phase of transient adhesion in microvessels requires adhesion molecules of the selectin family, whereas the tight adhesion that is a necessary prelude to capillary transmigration (Fig. 33.5) depends upon activation of molecules of the integrin family. Although current reports are a little confusing, it seems that under some circumstances eosinophils and monocytes may use components of the adhesion molecule repertoire (such as VCAM-1) that differ from those used by neutrophil granulocytes. This selective use of the adhesion molecule repertoire, together with the generation of chemokines with specificity for the different inflammatory cells, probably accounts for the selective accumulation of eosinophils in allergic responses and also for the differential timing of arrival of inflammatory cells at the inflamed site (neutrophils followed by monocytes and eosinophils). These selective mechanisms may also provide potential

targets for the development of new therapies in asthma and other allergic conditions.

There is *in vivo* evidence that these early recruitment mechanisms are operating in human asthma and its models. During the late response to inhaled allergen, a number of poorly characterized chemotactic factors for neutrophils and eosinophils can be detected in circulating blood [50,119,120]. Bronchial biopsies taken after allergen challenge show increased numbers of neutrophils, eosinophils and T cells [121,122]. Immunocytochemistry shows increased expression of ICAM-1, which correlates with the accumulation of leucocytes, and other molecules (see Table 33.2) involved in leucocyte adhesion to vascular endothelium [123,124]. Experimental studies in non-human primates have shown that monoclonal antibodies directed against ICAM-1 and E-selectin are able to attenuate the allergen-induced late reaction. The increased expression of ICAM-1 and other adhesion molecules on the surface of activated endothelial cells is likely to be mediated by cytokines such as IL-1, TNF- $\alpha$  and IL-5, which are probably derived from macrophages and T lymphocytes in the asthmatic airway [125]. However, these cells take several hours to synthesize these agents, whereas mucosal mast cells store preformed TNF- $\alpha$ , IL-5, IL-6 and other cytokines and chemokines in their granules and which can be released rapidly by cross-linking of the IgE receptor. Thus mast cells may make a variety of important contributions to early pathogenetic events in asthma.

#### Effector mechanisms (Fig. 33.6)

Once recruited to the airways, extravasated neutrophils and eosinophils are able to secrete a large number of histotoxic granule contents (see Chapter 27), including elastase, collagenase, MBP and EPO, many of which have been implicated in endothelial injury but which also contribute

**Fig. 33.5** Stages of granulocyte adhesion and emigration in microvessels.

**Fig. 33.6** Inflammatory response and asthma effector mechanisms. ROI, reactive oxygen intermediate.

to vascular responses and mucous secretion. They can also release a wide range of highly histotoxic reactive oxygen intermediates, including superoxide anion, hydrogen peroxide and hydroxyl radicals, and synthesize a range of important leukotrienes and prostanoids that cause airway narrowing, mucosal oedema and increased mucous secretion.

#### *Vascular responses*

The inflammatory response stimulates increased blood flow in the local airway microvessels which, in concert with increased vascular permeability, causes mucosal oedema and extravasation of plasma proteins. Mucosal oedema probably plays a major role in the airway narrowing and increased airflow resistance that characterizes severe asthma. Plasma-derived mediators like bradykinin cause bronchoconstriction, mucosal oedema, increased mucous secretion and, by inhibiting mucociliary clearance, contribute to mucous plugging of the airways. In chronic severe asthma, angiogenesis is probably involved in the process of airway remodelling. A number of inflammatory cytokines, including IL-1, FGF and PDGF, and the chemokine IL-8 have been implicated in angiogenesis.

#### *Airway smooth muscle*

There may well be no inherent change in smooth muscle contractility in asthma [126], although clearly many

mediators cause bronchoconstriction both directly and indirectly via release of neuropeptides and by influencing local nerve axon responses. There is also evidence of increased smooth muscle thickness, which may be the result of both hypertrophy and hyperplasia. Like vascular remodelling these changes are probably brought about by the action of growth factor cytokines such as PDGF.

#### *Epithelial injury and shedding*

Epithelial changes range from epithelial stimulation and minor injury to epithelial shedding and even extensive areas of denudation [4,122]. Many inflammatory cell products, including reactive oxygen intermediates and granule enzymes, are capable of injuring the airway epithelium, but the highly cationic eosinophil products MBP and EPO are particularly implicated. The fact that a diverse range of agents, such as viruses, allergies, chemicals and toxic gases, may lead to airway hyperresponsiveness may in part be explained by their common property of causing epithelial damage. Depending on the degree of epithelial injury, there may be a variety of consequences of relevance to the pathogenesis of asthma.

1 Injured and stimulated epithelial cells may themselves secrete a variety of important mediators, cytokines and chemokines, for example GM-CSF, IL-1, IL-8, RANTES. In responding to macrophage-derived IL-1 and TNF- $\alpha$  by secreting a range of chemokines, it is believed that the

epithelium, a rich source of IL-8 for example, may exert important amplification effects in the evolution of the inflammatory response.

2 Significant denudation of the epithelium may itself result in a variety of important secondary effects:

- (a) loss of the epithelial barrier function may permit direct access and influence of allergens and other proinflammatory factors (e.g. pollutants) on tissue cells including mast cells;
- (b) loss of airway epithelial cells reduces the ability to degrade peptide and kinin mediators and to secrete

epithelial-derived relaxant factor, which may help to maintain airway dilatation;

(c) sensory nerve exposure may promote inflammation and bronchoconstriction by local nerve axon reflex mechanisms [127].

(d) epithelial denudation may provoke proliferation of myofibroblasts normally located beneath the epithelial membrane, and proliferation of these cells and their secretion of extracellular matrix protein including collagen may contribute to the thickened basement membrane described in chronic asthma [128].

# ASTHMA: CLINICAL FEATURES

ANTHONY SEATON AND GRAHAM CROMPTON

## What is asthma?

The word 'asthma' is Greek, meaning 'breathless' or 'to breathe with open mouth'. Originally applied to shortness of breath of any cause, as in the description of the mode of death of metal miners ('from the disease the Greeks call asthma') by Agricola in 1556 [1], it has come to be applied particularly to episodic breathlessness due to bronchial disease. Sir John Floyer in his *Treatise of the Asthma* (1698) used the term in its general sense but confined himself largely to discussing the episodic type from which he himself suffered [2]. By the last century, as in another famous book by an asthma sufferer, Henry Hyde Salter's *On Asthma, its Pathology and Treatment* (1860), it was used specifically to describe this type of breathlessness [3]. Nevertheless, its application, as cardiac asthma, to left ventricular failure has only recently fallen into disuse.

The condition from which Floyer and Salter suffered is so distinctive that it may readily be diagnosed by non-medical people and its name is used in common parlance. It might therefore surprise the layman that there is so much debate about the definition of asthma, but such debate continues and is likely to do so unresolved. This is because, as far as can be seen, asthma results from the interaction of many genetic and environmental influences on the tone or reactivity of the airways, usually by causing inflammation; the response varies from individual to individual and from time to time. No single definition will ever cover all these variables in a way that is likely to be useful, particularly when one considers that asthmatic responses are not likely to be all-or-nothing phenomena but rather gradations of change on a continuum. As with other common diseases, the concept of what asthma is has been modified as knowledge of the disease increases. Originally it was acceptable to think of it in terms of a complex of symptoms and signs, then in terms of distinctive physiological and pathological features. Recently it has been popular to define it in terms of bronchial reactivity, although this leads to the uncomfortable recognition that some quite typically asthmatic subjects have normally

reactive airways between attacks. Of course, any definition in physiopathological terms requires arbitrary decisions about cut-off points between normality and asthma that make artificial distinctions between health and illness on that continuum.

It might therefore be appropriate to consider first why it is necessary to define asthma. From the point of view of the patient and the doctor, the name is unimportant; what matters is the management. Diagnosis leads to treatment and prognosis. For the former, it is necessary to demonstrate a response of the airflow obstruction to various drugs or to exclude exposure to a provoking agent, but for the latter it is desirable to fit the patient's disease into some broad category about which there is a body of medical knowledge on which attempts at prognosis may be based. Thus clinicians have tended to prefer definitions based on variability of symptoms and expiratory flow rates [4]. In contrast, pathologists, based on their experience particularly of fatal asthma, have inclined towards histopathological definitions, for example the presence of characteristic patterns in the sputum or of inflammation on bronchial biopsies or lavage [5,6]. Others, pursuing an interest in clinical pharmacology, have required tighter definitions based on physiological criteria; these definitions have often selected specific subgroups, for example in terms of exercise response [7] or the presence of evidence of cardiac stress in acute severe asthma [8]. Finally, epidemiologists have also needed to devise their own definitions for studies of asthma in populations; these range from positive answers to certain questions in a questionnaire to predefined responses to exercise or bronchial challenge [9,10].

Ultimately, it is conceivable that the propensity to develop asthma given appropriate environmental stimuli may be definable in terms of several chromosomal mutations. It is likely that there are separately inherited components of asthma, some genes leading to the development of atopy and others responsible for the many factors leading to bronchial inflammation and clinical asthma [11]. It has been suggested that the tendency for IgE

responses to occur is conferred by an 'atopy locus' on chromosome 11q [12], although there is dispute about this and other loci have been described [13,14]. However, studies of bronchial hyperresponsiveness in twins that have been adjusted for atopic status have suggested that environmental factors are at least as important as genetic [15,16]. Until we have more knowledge about the inheritance of atopy and asthma we will have to make do with more or less unsatisfactory definitions influenced by clinical, physiological and pathological factors that are inevitably imprecise. No harm will be done by this if physicians are aware of their reasons for using a particular definition or description of the disease, and the uncertainties surrounding it. A useful description of chronic asthma, based on the clinical, physiological and pathological findings, is

A common and chronic inflammatory condition of the airways. As a result of the airway inflammation the bronchi are hyperreactive and narrow readily in response to a wide range of stimuli. Whilst initially reversible, the inflammation may lead to irreversible obstruction to airflow.

This may then be qualified by a more quantitative definition in terms of, for example, sputum cytology, airway pathology, spontaneous change in flow rates, or responses to bronchodilators, steroids, exercise or bronchoconstrictors.

## Natural history

What happens to asthmatic children in adult life remains somewhat unpredictable [17]. It is a common observation that children with mild asthma tend to improve about the time of adolescence. Clinical and epidemiological studies indicate that 30–80% of asthmatics become asymptomatic

during puberty [18–22]. In the UK the prevalence of asthma or wheeze at the age of 7 has been assessed as 8.3% compared with 4.7% at the age of 11 and 3.5% at the age of 16 [23]. In a study of a 1958 birth cohort of over 18000 British children, Strachan and colleagues [24] showed a cumulative incidence of wheezy illness of 18% by age 7, rising to 43% by age 33. The prognosis in this cohort is shown in Fig. 34.1. Roughly one-quarter of those wheezing at age 7 were still wheezing at 33, and within this overall pattern there was a tendency for remission and later recurrence of symptoms in adult life. Furthermore, new wheezers added to the overall incidence throughout the study. Similarly, in a 25-year follow-up of 2500 primary school children in Scotland, Godden and colleagues [25,26] showed the incidence of new wheezy illness over this period to be 11% of those who had not wheezed in childhood and that these new incidences occurred steadily throughout the period. In a cohort study of Australian schoolchildren tested initially at the age of 8–10 years and then again at 12–14 years of age, the persistence of bronchial hyperresponsiveness at age 12–14 was found to be related to severity of disease at age 8–10, atopic status and parental asthma [27]. It has been suggested that improvement in asthma during adolescence may result from diminished clinical and immunological responsiveness directly related to hormonal changes [28], and that the effect of age on the prevalence of asthma in each sex may relate to differences in hormonal status, influencing airway size, inflammation and smooth muscle and vascular functions [29]. Factors found to predict persistence of asthma appear to be early age of onset of disease (younger than 3 years), infantile eczema (atopic status) and severe disease [30–32], as well as parental asthma [27]. When a cohort of children was assessed at the age of 20, about one-quarter were free from symptoms and had

**Fig. 34.1** Prognosis of children who developed asthma or wheezy bronchitis by age 7, each symbol representing 1% of such children. Solid circles represent children reporting asthma or wheeze in the previous year at ages 7 and 11, since their 16th birthday at age 23, and in the previous year at age 33. (From Strachan *et al.* [24] with permission.)

normal pulmonary function tests, half had occasional mild wheezing and some 20% had persistent or frequent wheeze or subnormal pulmonary function tests [33,34]. At the age of 28, 30% of those who were free from symptoms at the age of 21 had relapsed and had recurrent wheeze [35]. This supports the clinical experience that patients who appear to develop asthma in adult life often remember chest symptoms during childhood.

There has been much speculation about the genetic and environmental determinants of childhood asthma. Some of the factors related to the development of atopic sensitization that have been discussed include exposure to allergens, infectious diseases, or tobacco smoke early in life. The dietary habits of the mother may also be important but the effects of outdoor air pollution are likely to be unimportant [36]. This and other potential risk factors for asthma are discussed below. One cross-sectional study of elderly people with a history of asthma, detected in a random survey of a town's population, attempted to trace back the natural history of the disease by clinical questioning [37]. Even allowing for problems with memory and diagnosis, this illustrated the liability of asthma both to start and to remit at any age (Fig. 34.2).

Prospective population-based studies of the natural history of asthma in adults are few and, like the studies in children, are limited by difficulties in defining the disease. Most of the patients whose asthma persists from childhood have allergy to various aeroallergens, although the genuine new-onset adult asthmatics have allergic symptoms less commonly unless they have developed occupational asthma (see below). The term 'intrinsic' asthma was introduced in 1940 to emphasize that this type is distinct from allergic 'extrinsic' asthma with respect to the absence of an obvious precipitating exogenous cause [38]. The debate about whether intrinsic asthma is a distinct immunopathological entity persists [39]. Of a group of 85 children consecutively referred to an allergy clinic in Copenhagen when aged 5–15, 70 were seen 10 years later [40]; 24 originally had intrinsic asthma, i.e. normal serum IgE and no evidence of allergy from history, skin tests, radioallergosorbent test (RAST) and, in some, specific bronchial provocation tests; the remaining 46 were labelled extrinsic asthmatics. At the 10-year follow-up, 60 (24 intrinsic and 46 extrinsic) had current symptoms and 54 were receiving maintenance therapy. In the patients with intrinsic asthma, outcome appeared to be predicted by a combination of initial frequency of symptoms, initial forced expiratory volume in 1s ( $FEV_1$ ), active smoking and age at onset of symptoms. In the extrinsic group, initial  $FEV_1$  was the strongest predictor for outcome and it was suggested that these differences pointed to different pathogenic mechanisms in the two types of asthma. However, a careful follow-up study of a cohort of wheezy children in Australia, to the age of 28, concluded that there is no difference in outcome between asthma and 'wheezy

**Fig. 34.2** History of asthma symptoms in 27 subjects found in a random sample of people aged 70 or more from a South Wales town. (From Burr *et al.* [37].)

bronchitis' in childhood [33,35]. In the view of the authors, asthma is best thought of as an inflammatory disease of the airways with multiple precipitating causes acting throughout life. In those most strongly predisposed genetically, atopy is a dominant factor and such individuals tend to present early in life. Those presenting in adult life are somewhat less frequently atopic, and factors such as smoking, poor diet, occupational exposures and infections appear to be more relevant to the aetiology than in childhood.

Several studies have investigated mortality from asthma. Interest in this subject was aroused by a sharp rise in mortality in the UK, New Zealand and other westernized countries (but not the USA) in the mid-1960s [41]. Among young people, death rates attributed to asthma

rose to about 2 per 100 000 population per annum, subsequently falling to the more usual levels of about half that (Fig. 34.3). In New Zealand there was a second rise in mortality in the 1970s to about 4 per 100 000 [43]. These changes stimulated a number of clinical and case-control investigations of possible causative factors; excess use of bronchodilators and inadequate use of corticosteroids have been suggested as likely ones [44–50]. The possible role of  $\beta$ -agonist bronchodilators and the increase in mortality, particularly in New Zealand, has caused most concern and has stimulated much debate. The New Zealand 'epidemic' was originally attributed to fenoterol [51]. However, the explanation is not straightforward; although the drug was also available in The Netherlands and the UK, the asthma mortality rates in these countries had returned to the levels observed before 1940 and remained there. Taken together, the time trends suggest a causal relationship between death from asthma and inhalation therapy with  $\beta$  agonists. However, others have rejected the view that the use of  $\beta$  agonists, one of the cornerstones of asthma treatment, is potentially dangerous [52], the argument being that  $\beta$  agonists merely served as a marker of patients with a poor prognosis. There are two main questions that remain unanswered with regard to  $\beta$  agonists: does regular inhaled treatment with these drugs make asthma worse or increase bronchial hyperreactivity either during therapy or after withdrawal and is this form of treatment dangerous when given to, or taken in excess by, the hypoxaemic asthmatic? Of course,  $\beta$ -agonist therapy cannot be an explanation of the increased prevalence of asthma, and whether it has had any role in the fluctuation in severity of patients with severe disease over

the years remains to be answered. There is evidence from experiments with animals that  $\beta$  agonists are much more toxic in the presence of hypoxaemia [53], and this has tended to be forgotten. It has been reported that similar findings resulted when human volunteers were studied in a hypoxaemic state [54]. In general the message from all studies is the slightly depressing one that death commonly occurs as a result of failure by patient or doctor to appreciate the severity of the condition or to take appropriate therapeutic action until too late. The pros and cons of  $\beta$ -agonist therapy are discussed in more detail in Chapter 35.

The actual risk of an asthmatic patient dying of the disease clearly depends on such factors as age, severity of disease, and availability and quality of medical care. Asthma deaths are rare in children, accounting for just over 1% of total deaths [55]. Thereafter, the risk increases exponentially with age (Fig. 34.4). Interpretation of geographical variations and time trends in mortality usually concentrates on deaths among children and adults up to age 35 where there is more confidence in the accuracy of diagnosis. However, only 10% of deaths occur in this age group and the rates for all countries where reliable data are available were similar in the 1990s at 1 per 100 000 or fewer [56].

## Pathology

### Gross pathology

The greatest amount of information on the pathology of the lungs in asthma originally came from necropsy studies of patients who had died from acute attacks [57–61]. However, some information has also been obtained from lungs of asthmatic patients dying of other causes while in remission and from the study of bronchial biopsies, bronchoalveolar lavage (BAL) fluid and sputum from asthmatics. Recently, developments in bronchoscopic techniques and methods to enable patients to produce sputum, together with electron microscopy, have allowed a much more detailed knowledge of pathological airway morphology to be obtained from living patients with mild, moderate and severe disease.

The lungs of asthmatic patients who have died of incidental disease may show the features seen in those who have died of asthma but in a less advanced form. There is usually some overdistension and plugging of airways. In contrast, patients with chronic asthma may die with lungs that look grossly quite normal, despite having had intractable symptoms in life [62]. The lungs of patients who have died of acute asthma are voluminous and do not collapse when the chest is opened at autopsy. When cut, thick and tenacious mucus is seen to be occluding almost all small- and medium-sized airways, but this can extend into the large bronchi. There may be small focal areas of

Fig. 34.3 Trends in mortality from asthma in 5–34 year olds in six countries, 1959–79. (From Jackson *et al.* [42].)

**Fig. 34.4** Age-specific asthma mortality rates, males and females combined, England and Wales 1958–95. (From Lung and Asthma Information Agency factsheet 97/3, with permission of Professor Ross Anderson.)

pulmonary collapse. Occasionally, when death has been sudden, widespread airway plugging is absent. Although the lungs are hyperinflated, there is usually no macroscopic evidence of emphysema.

### Bronchial biopsies

Much has been learned about the pathological processes in asthma by examination of bronchial biopsies and BAL fluid. These investigations are safe providing that they are performed by an experienced bronchoscopist and that published recommendations are followed [63,64]. The airway mucosa sampled by biopsy comprises surface epithelium and its supportive subepithelial tissue, often referred to as the lamina propria.

Data obtained by biopsy have shown beyond doubt that asthma is an inflammatory condition, and have provided the basis for the validation of less invasive techniques, such as airway lavage, bronchial brush biopsy and the examination of sputum, either produced spontaneously or induced. Pioneering studies of relatively large biopsy samples obtained using the rigid bronchoscope revealed the mucosal inflammation of asthma, contrasted the pathological appearances in asthma and chronic bronchitis and demonstrated the efficacy of inhaled corticosteroid therapy [65–68]. These studies also revealed the marked airway epithelial disruption in asthma, now accepted as a characteristic pathological feature of the disease even though described as early as 1962 [69]. With the advent of flexible fibreoptic bronchoscopy as a research tool there has been an explosion of interest in the pathological changes in the bronchial epithelium of the asthmatic patient [70]. Initial electron microscopic studies of biopsies

in mild chronic asthma reported the involvement and degranulation of mast cells [71], highlighted a controlling role for the lymphocyte in the inflammatory response, and demonstrated an association between loss of surface epithelium and airways hyperresponsiveness [72]. Most, if not all, of these pathological changes had previously been described in autopsy studies of patients dying from asthma [57,59–61]. These features of inflammation were shown to be present even in patients with newly diagnosed asthma or asthma of apparently recent onset [73].

Studies of bronchial biopsies together with clinical observations have led to the conclusion that early intervention with anti-inflammatory therapy is the most rational approach to treatment of asthma [74]. Homogeneous thickening of the basement membrane, also referred to as the lamina reticularis, is a constant pathological finding and has been shown to occur early in the disease process [72,75], in contrast to the lack of this change in chronic obstructive airways disease [76,77]. Basement membrane thickening in asthma is assumed to represent subepithelial fibrosis and is associated with close proximity of myofibroblasts [75,78]. Studies of bronchial biopsies from large numbers of patients have revealed activation of the CD4<sup>+</sup> subset of T lymphocytes and also eosinophils [79,80]. There appears to be a negative correlation between eosinophil activation and bronchial reactivity [80]. Observation of upregulation of gene expression for the proinflammatory cytokine interleukin (IL)-5, in association with the CD4<sup>+</sup> T lymphocyte, particularly in symptomatic patients [81], has led to the concept of a prevailing Th2 allergic inflammatory profile in asthma in which IL-4, IL-5 and IL-10 predominate [82,83]. Verification of these find-

ings has been achieved by using reverse transcriptase-polymerase chain reaction techniques. The profile of inflammatory cell and cytokine gene expression appears to be similar in different types of disease, such as atopic (extrinsic), non-atopic (intrinsic) and occupational asthma, although there is some debate about the role of IL-4 in intrinsic asthma [84–87].

Bronchial and nasal biopsies have been studied after exposure to allergens. The use of immunohistological and molecular (*in situ* hybridization) techniques has supported the involvement of CD4<sup>+</sup> T cells, mast cells and eosinophils, together with IL-4, IL-5 and IL-10 [82,88–90]. There is also great interest in the role of cell-surface adhesion molecules in the epithelial inflammatory events of asthma and allergy [91–93]. Myofibroblast numbers increase in response to allergen and transitional ultra-structural forms between fibroblasts and bronchial smooth muscle cells are found [94]. This suggests a possible mechanism to explain the increase in bronchial smooth muscle that is a characteristic feature of the airway wall remodelling found in severe asthma [95]. Exposure to toluene diisocyanate (TDI) in workers who develop occupational asthma resembles allergen exposure in many aspects, although in addition there is a marked recruitment of neutrophils [86,96,97].

Bronchial biopsies have been used to assess the effects of various treatments on the asthmatic bronchial epithelial inflammation. Inhaled corticosteroid therapy has been shown to improve these pathological changes [98–100] and the changes in bronchial biopsy appearances have been associated with symptomatic improvement. Similar improvements in symptoms and bronchial epithelial pathology have been reported in non-allergic asthma [101]. The anti-inflammatory properties of some other drugs have been assessed by bronchial biopsies, and oral theophylline has been shown to have some activity after 6 weeks of treatment compared with placebo in that it decreased cell numbers and the expression of IL-4 [102].

Bronchial biopsies sample mainly the proximal airways and it is somewhat surprising that so much inflammation and remodelling has been found in the large airways in asthma. There is some evidence that the changes in large airways reflect more peripheral pathology in the small airways, and perhaps also in the alveoli [103]. Since biopsies sample such a small fragment of epithelium, one would expect considerable variation between specimens, such that very large numbers of patients would have to be studied to obtain any meaningful data. However, it is reassuring that there seems to be larger intersubject than inter-biopsy site variation, and it has been estimated that study of groups numbering 15 patients should provide sufficient statistical power to detect most of the changes of interest in biopsies from inflamed airways [104].

The inflammatory cell that predominates within the

surface epithelium may be different to that in the tissue beneath it, and cells harvested from the bronchial lumen by BAL may not reflect the cell populations in any section of the bronchial mucosa. This may partly explain differences between biopsy and BAL findings. The correlations between cellular findings of lavage and biopsy specimens are poor and bronchial biopsy remains the gold standard [70]. Bronchial brush biopsies are being used to harvest cells from the bronchial mucosa and may in the future be of value in the assessment of the degree of pathological change in asthma and its response to treatment, if there proves to be a good correlation between these and bronchial biopsies.

### Sputum

Sputum is characteristically viscous. When held up to the light, pale green or white streaks can often be seen in the mucus and, when teased out, these can be shown to be bronchial casts (Fig. 34.5). Recently there has been considerable interest in the cell content and immunobiochemical characteristics of sputum from asthmatics [105]. Sputum is defined as expectorated lower respiratory tract secretions and is composed of fluid and cellular components, including macrophages, bronchial epithelial cells and inflammatory cells. As well as containing water and inorganic ions, it also contains non-dialysable components such as albumin, lysozyme, glycoproteins (including immunoglobulins, macroglobulin, complement and proteases), proteoglycan and lipids, perhaps in part derived from surfactant. Proteins and glycoproteins appear to occur in considerably higher concentration in asthmatic than in bronchitic sputum [106]. IgE is also increased, even in

Fig. 34.5 Bronchial casts teased out from the sputum of a patient with asthma.

non-atopic asthma [107]. When expectorated, sputum is always mixed with saliva, composed mainly of fluid, squamous epithelial cells and oropharyngeal bacteria. Sputum contaminated with saliva may be examined for evidence of bronchial inflammation [108], although it is apparent that examination of sputum *selected* from the expectorate is preferable [109–111]. In asthmatic subjects, sputum may be induced by the inhalation of an aerosol of hypertonic saline after pretreatment with inhaled salbutamol [105,112].

#### *Sputum eosinophils*

Sputum eosinophilia is a hallmark of asthma and was shown to be associated with the disease almost 100 years ago. The eosinophil is probably the major effector cell in asthma [113]. Eosinophils arise from a bone marrow-derived progenitor cell and circulate via the bloodstream to the airways [114]. Under the influence of cellular adhesion molecules and cytokines the eosinophils migrate across the endothelium to the airway lumen. Sputum eosinophils in asthma are in an activated state, expressing cleaved eosinophil cationic protein (ECP) and CD11b [115]. Cell adhesion molecules ICAM-1 and HLA-DR are present in sputum eosinophils but not blood eosinophils, and these may allow migration across the endothelium and facilitate interaction with other immunocompetent cells such as T lymphocytes [116]. The eosinophil plays an important role in the pathogenesis of asthma, and sputum eosinophil counts reflect disease severity [112]. Eosinophils occur spontaneously and after allergen challenge in asthma [108,113–118]. Thus eosinophil counts and measurement of their products in sputum have a potentially important role in acting as objective markers of bronchial inflammation in asthma. Sputum eosinophils, and the biochemical markers ECP, albumin and fibrinogen, correlate with the diagnosis of asthma [108,112,117] but not with airway hyperresponsiveness in the absence of symptoms [119]. There is also correlation with disease activity and the magnitude of response following allergen challenge [112,114,120]. Patients with sputum eosinophilia tend to respond well to corticosteroid therapy [118,121,122].

#### *Sputum mast cells*

There is in the region of a 10-fold increase in the number of mast cells in spontaneously produced and induced sputum from asthmatic patients compared with normal subjects or patients with chronic bronchitis [112,117]. Mast cell counts are highest during exacerbations of asthma and increase after allergen challenge [120]. There is no correlation between sputum mast cell numbers and markers of disease severity such as FEV<sub>1</sub> and bronchial provocation tests, whereas in BAL and bronchial brushings mast

cells appear to correlate with airway responsiveness [123,124]. Mast cell mediators such as tryptase and histamine can be detected in induced sputum, although there are no major differences between normal and asthmatic subjects [108].

#### **Bronchoalveolar lavage**

BAL is a useful research technique but its role in the investigation and assessment of asthma has yet to be established. Together with other research techniques it has contributed to the understanding of disease mechanisms and treatment effects [125]. Interlobar variability of BAL findings has been assessed. Eosinophil and neutrophil counts are consistent between two lobes from the same individual, indicating that a single-site lavage yields fluid representative of the whole lung; however, there is poor agreement between soluble markers such as the neutrophil product myeloperoxidase and the eosinophil marker ECP [126]. In stable asthma there are increased numbers of eosinophils and mast cells in BAL fluid compared with normals [123], and the same pattern of BAL cell increases has been found in allergic and non-allergic asthma [124]. BAL eosinophils correlate with asthma symptoms, airflow obstruction and airway responsiveness [123,127]. Allergen challenge causes an increase in BAL eosinophils [128] and in eosinophil activation. This is accompanied by increased gene transcription for those cytokines that control eosinophilic function, IL-5 and granulocyte-macrophage colony-stimulating factor (GM-CSF) [127]. Treatment with prednisolone reduces BAL eosinophils and IL-5 gene transcription at the same time as symptoms are improved [129]. In general there is a correlation between the severity of airways responsiveness in asthma and the numbers of eosinophils, mast cells and their mediators in BAL [130]. In a comparison of induced sputum, bronchial washings and BAL in 16 patients, it was concluded that induced sputum is rich in neutrophils and eosinophils and poor in lymphocytes, suggesting an origin in the larger airways. It was also concluded that induced sputum adequately reflects the findings in fluid collected by BAL [131].

#### **Histological features**

Many of the microscopic features of the asthmatic airway are mirrored in the sputum. The airways of patients who have died from asthma characteristically show smooth muscle hypertrophy and thickening of the basement membrane (Fig. 34.6). The mucous glands are often considerably enlarged. The submucosa is oedematous, infiltrated with eosinophils and lymphocytes, and contains dilated capillaries with swollen endothelial cells. Mast cells may be found in the submucosa, especially in association with small vessels. Internal to the basement

(Courtesy of Dr Peter Johnston, Department of Pathology, University of Aberdeen.)

membrane, the mucosa may have been almost totally destroyed. It is often very oedematous, the oedema being associated with a denudation of the internal surface cells leaving only basal cells. Remaining epithelium is often metaplastic, showing a stratified non-ciliated structure with prominent goblet cells. Eosinophils are a conspicuous feature of the inflammatory exudate. Within the airway lumen lies thick tenacious mucus that under the microscope is seen to contain strips of desquamated epithelial cells (Curschmann's spirals), eosinophils, isolated metaplastic epithelial cells or clumps of cells (Creola bodies) and crystalline material consisting largely of major basic protein derived from eosinophils (Charcot-Leyden crystals) [5,60,132–134]. These plugs may occur throughout airways of all sizes, sometimes reaching the smallest respiratory bronchioles, possibly by aspiration.

The consequences of these histological abnormalities may be found in the sputum of patients with symptomatic asthma, and are not confined to patients with severe disease (Fig. 34.7).

In contrast to the dramatic evidence of disease in patients dying of asthma, much less marked yet nevertheless similar changes are found in patients who have suffered from chronic asthma but have died from another cause [61]. There may be no plugging and little or no smooth muscle hypertrophy, and relatively few eosinophils in patients who have been treated with corticosteroids. Basement membrane thickening is the only characteristic feature, although mucosal and submucosal infiltration with lymphocytes and plasma cells, mucous gland hyperplasia and some peribronchiolar fibrosis may be seen.

## Pathogenesis

An understanding of the pathogenesis of asthma requires answers to two questions: what predisposes an individual to show the characteristic pathophysiological airway changes, and how do the known provoking stimuli cause these changes? With respect to the first question, it is a matter of common observation that genetic factors must be important, particularly when the asthma is accompanied by the manifestations of atopy. This is discussed later. However, it is now clear that environmental factors may initiate the asthmatic process, rather than simply provoke attacks in someone already predisposed. The differences in prevalence of asthma in populations transferred to westernized from more primitive societies, between people living different lifestyles in the same country, and the secular changes in prevalence noted in developed countries over the past three decades all suggest an important environmental factor, as does the evidence that certain chemicals may act as initiators of asthma (which persists after exposure has ceased) in some workforces. Similarly, it is also a matter of common observation that adult asthma may be initiated by upper respiratory tract infections, sometimes for a short time but not infrequently permanently. Studies of bronchial reactivity and of responses to inhalation of irritant substances suggest that the liability of airways to constrict in response to such stimuli is distributed normally in the population, and is variable over time, indicating perhaps that all of us may be liable to develop some of the features of asthma in response to stimuli of appropriate severity.

The answers to the second question, namely the mechanisms whereby a stimulus provokes the airway reaction, lie in the study of the cellular, immunological and biochemical control of airway function. Any hypothesis

must explain why similar reactions occur in response to infection, allergic challenge, chemical challenge, exercise, sleep, emotion, ingestion of certain drugs and, indeed, for no obvious reason at all. It must also explain the presence of the characteristic histological and biochemical changes in the airways and their exudate, and must take account of the recognized patterns of response (and, in some cases, failure to respond) to therapy. Not surprisingly, understanding of the mechanisms of asthma remains incomplete; nevertheless, much research effort has been devoted towards this end and much interesting, if somewhat confusing, information has been obtained. In the following discussion, this evidence is considered under the headings of cellular mechanisms, mediators, neural mechanisms and bronchial smooth muscle function. There is evidence that all these factors, which interrelate with each other, play a part in producing the pathophysiological changes of asthma. Before embarking on this discussion, some relatively simple models of asthma are described.

## Simple models of asthmatic mechanisms

### Exercise and hyperventilation

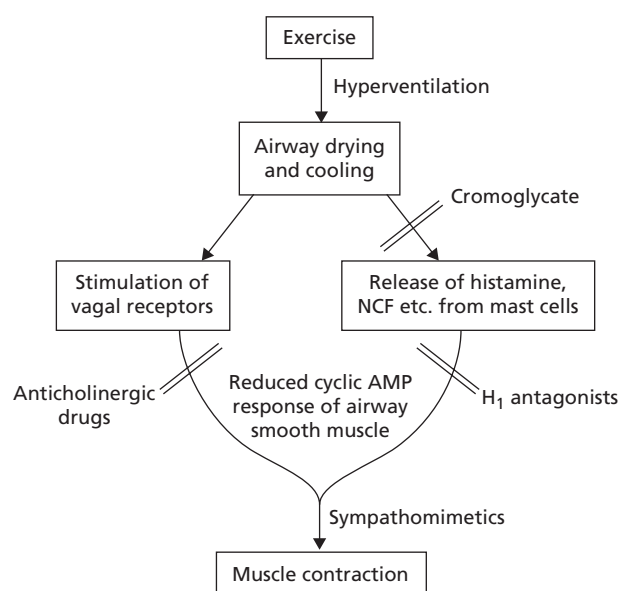

The simplest model of asthma, and one that has been much used in research, is the induction of airflow obstruction by exercise or breathing cold air [135,136]. In most but not all patients with clinical asthma, either of these manoeuvres causes an increase in airways resistance that lasts for some 30 min. This gave rise to the hypothesis that hyperventilation, with its associated drying and cooling of the airways, leads to the release of bronchoconstrictor substances or to a neural bronchoconstriction reflex, or to both [137,138]. Only rarely has exercise been shown to provoke

a delayed and more prolonged reaction [139,140], suggesting that in most cases if release of mediators occurs these are likely to be short-acting bronchial muscle constrictors rather than agents that lead to bronchial wall inflammation and oedema. This concept is supported by studies which have shown that once an attack has been provoked by exercise and the subject has recovered, further exercise does not provoke increasingly severe attacks [141]. On the contrary, subjects may be able to continue exercise and find that the asthma improves.

Thus exercise provocation provides an opportunity to study the mechanisms of the immediate component of the asthmatic reaction. Two approaches have been used: search for release of mediators and attempts to block the reaction with drugs. Studies of arterial total and plasma histamine have shown raised baseline levels (compared with controls) that increase during exercise [142–144]; however, similar rises have been described in exercising control subjects [143]. Rises in the levels of neutrophil chemotactic factor during exercise have also been observed [139,145]. Since asthmatic airways show increased sensitivity to histamine, it is likely that histamine release during exercise contributes to the production of airflow obstruction; this concept has been supported by demonstration of a protective effect of selective  $H_1$ -receptor antihistamine inhalation prior to exercise [146]. The exercise response can be blocked by inhaled  $\beta$ -sympathomimetic drugs and, in a proportion of cases, by sodium cromoglycate (cromoglycate) and high-dose inhaled antiparasymphathetic drugs [147–149]. The former observation is explicable on the basis of bronchodilatation, although it is interesting that studies of cyclic AMP levels show that subjects developing exercise-induced asthma do not show the marked rise seen in the non-asthmatic exercise response, indicating a reduced sympathetic response to exercise in such subjects [150–152]. Furthermore, the blocking effect of antiparasymphathetic drugs suggests that vagal reflex mechanisms may be involved in some cases.

Thus, what appears superficially to be a simple model of part of the asthmatic reaction can be seen to involve release of histamine and other mediators, reduced sympathetic response and sometimes parasympathetic reflexes. This leaves unexplained both the mechanisms whereby the response is triggered and also the increased susceptibility of airway muscle to histamine stimulation. Perhaps the clue to the latter lies in the failure of the cyclic AMP response, an area of research that has lately been neglected in favour of search for mediators. The mechanism of the trigger seems to be related to hyperventilation and associated drying and cooling of airways, although this is a feature of exercise common to asthmatics and non-asthmatics; the reason that one responds and the other does not may lie in differences in the reactions of mast cells or neural receptors in airway mucosa to these stimuli.

**Fig. 34.8** Mechanisms of exercise-induced asthma showing the three possible pathways: mediator release, vagal stimulation and reduced sympathetic drive in smooth muscle. The most effective preventive drugs are sympathomimetics, although  $H_1$  antagonists and anticholinergics are also moderately effective in adequate doses. Steroids have only a rather weak long-term preventive effect. (NCF, neutrophil chemotactic factor.)

Here, again, the reduced cyclic AMP response may be an important clue. A suggested scheme for the mechanisms of exercise-induced asthma is shown in Fig. 34.8.

### Antigen challenge

Another model of the asthmatic reaction that has been much studied is the response to inhalation of antigen. This differs from the response to exercise in one important particular: it commonly comprises an immediate and a delayed reaction (Fig. 34.9). The immediate reaction is similar to that occurring after exercise and is blocked by sympathomimetics and cromoglycate but not by corticosteroids. The delayed reaction usually starts during recovery from the immediate (which is shown by the fact that flow rates rarely rise to baseline levels between the two), is prolonged up to 24 or 48 h, and may be followed by a period of increased bronchial reactivity or even by recurrent asthma attacks for several days [153]. It is usually blocked by corticosteroids and cromoglycate but not by sympathomimetics [154–156]. An identical dual reaction may occur in response to inhalation of low molecular weight chemicals such as isocyanates or colophony that are known to cause workplace asthma, probably by combining as haptens with plasma proteins.

This dual reaction and its modification by drugs are clearly suggestive of immediate bronchial muscle constriction followed by a progressive bronchial wall

inflammation and mucosal swelling. Moreover, the persistence of the late reaction and the fact that it is only partly responsive to sympathomimetic drugs suggest that it is a more realistic model of the situation in most patients with attacks of asthma. It is reasonable to hypothesize that the initial antigenic stimulus results in the release of both short-acting and long-acting mediators, which initiate both reactions; it is known that the combination of antigen molecules with pairs of IgE antibody molecules on the surface of mast cells leads to release of such substances [157]. Studies of blood and urine levels of histamine and its metabolites and of neutrophil chemotactic activity after bronchial challenge with antigen have shown an initial rise, consistent with the hypothesis [158,159]. Furthermore, bronchial lavage studies during the late reaction have shown evidence of an influx of eosinophils and ECP

**Fig. 34.9** Response of peak flow rate to challenge with toluene diisocyanate vapour from varnish showing immediate and late reactions.

**Fig. 34.10** Mechanisms of response to inhaled antigen. Mast cell degranulation provoked by surface binding of IgE–allergen complex releases both short-term mediators, which cause immediate smooth muscle constriction, and also interleukins and

at that time, indirect evidence for the release of eosinophil chemotactic factor during the earlier part of the reaction [160]. The cellular and humoral mechanisms of the late response are discussed further in Chapter 33.

Thus, as far as the evidence goes at present, antigen challenge may be regarded as a means of releasing short-acting and delayed-acting mediators, almost certainly from mast cells, which produce immediate bronchoconstriction and later bronchial wall, predominantly eosinophilic, inflammation. In most subjects, the basic requirement is atopic sensitization, with the ability to react to antigen with an IgE antibody response. These reactions are illustrated in Fig. 34.10.

### Challenge with mediators

In concept, the simplest model of asthma results from the identification of mediators of the reaction and their use in a challenge test. Histamine is the one most studied; its inhalation provokes an immediate increase in airflow obstruction that can be blocked by prior administration of inhaled  $H_1$ -receptor but not  $H_2$ -receptor antagonists [161,162]. The response to inhaled histamine varies in the population, most people showing very little reaction, some showing a moderate reaction and a few being very sensitive [163,164]. There is no clear distinction between reactors and non-reactors, rather a gradation. Moreover, some people show reactivity at one time and much less or none at others [165]. The test may therefore be used as an index of bronchial reactivity but does not in itself shed much light on the mechanisms of asthma.

Methacholine, a parasympathomimetic agent, affects airflow similarly to histamine and is also used as a non-specific indicator of bronchial reactivity [166]. Similar effects have been demonstrated by inhaled prostaglandin ( $PG$ ) $D_2$  and  $PGF_{2\alpha}$  and leukotriene ( $LT$ ) $C_4$  and  $LTD_4$ , which are more potent than histamine on the asthmatic

tumour necrosis factor  $\alpha$ , which upregulate adhesion molecules. These in turn cause chemotaxis of neutrophils and eosinophils, leading to airway inflammation and the later more prolonged reaction.

airway [167–171]. The leukotrienes exert a rather slower and more prolonged effect than does histamine.

All these studies indicate that such chemicals are able to provoke airflow obstruction much more readily in people with hyperreactive airways than in those without. They thus suggest that at least part of the mechanism of asthma is related to reactivity of airways rather than excessive release of mediators. However, it is possible that prolonged exposure to these or other mediators may in some way sensitize the airways. This subject remains an area of active research.

### Immunological mechanisms

While it is clear that what would be regarded as classical immunological reactions are not responsible for all the manifestations of asthma, there is little doubt that they are among the important factors in the genesis of the disease in atopic individuals. Such people have the inherited ability to produce IgE antibody in response to allergenic stimulation (see p. 939). The reaginic antibody described as the important factor in allergy by Prausnitz and Kustner in 1921 [172] was characterized as IgE in 1966 [173]. It is a glycoprotein of molecular mass 190 kDa, with two heavy ( $\epsilon$ ) chains bound by disulphide bridges to two light ( $\kappa$ ) chains. It is synthesized and secreted by B lymphocytes and plasma cells in response to specific antigen challenge, the response being under the control of T helper and suppressor lymphocytes [174]. In common with other immunoglobulins, IgE has two functional components, an Fc (crystallizable) part responsible for eliciting the biological response and two identical Fab (antigen-binding) parts responsible for attachment to the allergen.

The simplest concept of allergic asthma is that an antigenic response to allergen provocation results in the binding of an antigen with multiple binding sites to the Fab part of the IgE molecule. At least two of these IgE molecules bound to a common antigenic particle then link to Fc-binding sites on a basophil or mast cell, leading to a sequence of events in the cell resulting in the release of mediators [174]. It is now known that this is only part of the story and that other cells, including macrophages, eosinophils, lymphocytes and platelets, also have IgE Fc receptors and may well play a part in the pathogenesis of the disease. Much is known of the changes occurring in the mast cell membrane in response to antigen–antibody binding [175]. The bridging of two Fc receptors by the IgE–antigen complex leads to two parallel biochemical events, the influx of calcium into the cell and the conversion of ATP to cyclic AMP. Cyclic AMP, in the presence of an appropriate calcium concentration, activates protein kinases that phosphorylate the specific enzymes concerned with histamine release. The conversion of ATP to cyclic AMP is promoted by augmentation of the activity of adenylate cyclase by the bridging event, this enzyme in

turn cleaving the ATP molecule. The influx of calcium is governed by the methylation, again in response to the bridging event, of phosphatidylethanolamine to phosphatidylcholine. This phospholipid migrates to the cell surface and the consequent change in the structure of the cell membrane allows the influx of calcium. The same biochemical reactions probably result in the release of other preformed mediators, including the low molecular weight eosinophil chemotactic factor [176].

Antigen–antibody binding to the surface of mast cells or basophils can also lead to the release of mediators derived from arachidonic acid [177]. This substance is stored in the phospholipids of the cell membrane and is released by activation of phospholipase during influx of calcium following the bridging event described above. Platelet-activating factor (PAF) may also be derived by similar mechanisms from basophils and other cells [178–180].

The basophil and mast cell are not the only cells involved in the release of mediators of asthmatic inflammation [181,182]. Macrophages, eosinophils, lymphocytes and platelets also have receptors for the Fc portion of IgE. Macrophages have been shown to release reactive oxygen intermediates, lysosomal enzymes and derivatives of arachidonic acid in response to surface binding of multiple IgE molecules bound to antigen. Eosinophils are attracted by the binding of IgE–antigen complexes to mast cells and this may lead to release of the major basic protein, which is very toxic to airway epithelium [183,184]. T-lymphocyte IgE receptors may play a role in the control of IgE production by B lymphocytes via a process of negative or positive feedback [181,185]. Platelet receptors may facilitate the secretion of serotonin.

Thus the events related to the immunological induction of asthma may be summarized as follows. In an individual with a predisposition to react to antigen challenge by production of IgE from B lymphocytes, such challenge leads to the formation of IgE–antigen complexes that bind to the surface of basophils, mast cells and macrophages in particular. Release of preformed mediators, such as histamine and eosinophil chemotactic factor, leads to bronchoconstriction and an influx of eosinophils. Release of other inflammatory mediators leads to progressive oedema and infiltration of the bronchial wall, while toxic substances such as major basic protein and PAF cause epithelial cellular disruption. Enzymes released from macrophages may be responsible for the characteristic separation of the epithelium from the basement membrane.

### Immunopathogenic mechanisms

It is, of course, of some interest to speculate why the human organism should have evolved such a sophisticated mechanism of self-injury; the answer must lie in a biological advantage obtained by those with the ability to produce IgE in these amounts [186,187]. One simple and

perhaps partial explanation is that this may be related to the role of IgE in defence against parasitic organisms, by facilitating the binding of such organisms to cells such as eosinophils and macrophages able to secrete substances toxic to the invaders. More interestingly, it has been suggested that the reason may be found in the need for the fetus to protect itself from attack by the mother *in utero* [188]. This concept relates to the fact that the propensity to mount an IgE-mediated allergic reaction depends upon a predominant differentiation of T-helper lymphocytes into the Th2 subtype responsible for production of cytokines, especially IL-4, which stimulate B lymphocytes to produce IgE. It is argued that undifferentiated helper T cells may produce clones of predominantly Th1 or Th2 type. The former secrete, *inter alia*, interferon (IFN)- $\gamma$ , important in defence against many infecting organisms, including viruses and intracellular bacteria, but which is also very toxic to the conceptus; the latter produce IL-4 and IL-5. These cytokines may counter the effect of IFN- $\gamma$ , and it appears that the natural state of the fetus is skewed towards production of Th2 cells. This bias persists in infant life, but in the majority is displaced by a predominantly Th1 clone as the baby develops. At least one stimulus to this may be infections acquired in childhood, which promote the development of Th1 clones. Thus it has been argued that early childhood infections, perhaps particularly the intestinal infections associated with relatively poor living conditions, may switch newborn children from an atopic to a non-atopic potential. This concept fits well with evolutionary theory and provides an explanation not only for the persistence of atopy but also possibly for the increase in asthma and allergic diseases.

The interrelationships of Th1 and Th2 cells and their

cytokines are complex and far from fully understood. It is thought that the initial stage of differentiation involves the dendritic cell, which is derived from CD34 lymphocytes and which is present in asthmatic airway walls [189]. Cytokines, including tumour necrosis factor  $\alpha$  and IL-4, cause dendritic cells to express receptors for antigen; after binding with this, they migrate to local lymph nodes where they present their major histocompatibility complex (MHC) class II antigens to naive T lymphocytes, leading to Th2 differentiation. In contrast, infections leading to secretion of IL-12 from dendritic cells can influence naive T cells to differentiate into Th1 cells. In atopic disease, allergen is processed and presented by the dendritic cells to T lymphocytes, which then differentiate into the Th2 phenotype; this secretes IL-4 that further aids in the maturation of the Th2 cell and in switching B lymphocytes from production of IgM and IgG to IgE. In contrast, IFN- $\gamma$  from Th1 cells, driven by IL-12, downregulates Th2 differentiation and IgE production. The Th1 phenotype is associated with cell-mediated cytotoxicity and delayed-type hypersensitivity, and it is likely that early induction of high levels of IFN- $\gamma$  may reinforce T-cell differentiation in the Th1 direction, leading to unresponsiveness to allergens.

Whatever the precise relationships between T lymphocytes and their cytokines, it is apparent that there are opportunities for understanding the reasons why one person develops asthma and another does not; even more importantly, this may lead to explaining the reasons for the rise in atopic diseases as societies become wealthier and more sophisticated. This is discussed below. A simplified summary of the proposed cellular and humoral mechanisms in the allergic asthmatic reaction is shown in Fig. 34.11.

**Fig. 34.11** A summary of the main proposed cellular and humoral mechanisms in the allergic asthmatic reaction. Allergen fragments are presented to T lymphocytes by the major histocompatibility complex (MHC) class II antigens on dendritic cells. They are then presented to B cells, which under the

influence of interleukins from T cells produce allergen-specific IgE. This then binds to allergen on the surface of mast cells, leading to release of mediators and the pathological features of the asthmatic airway.

**Fig. 34.13** Biosynthesis of some of the prostaglandins.

capacity to produce different metabolites. LTD<sub>4</sub>, LTE<sub>4</sub> and LTC<sub>4</sub> (which together were originally described as slow-reacting substance of anaphylaxis, SRS-A) are most potent in terms of bronchial smooth muscle constriction and LTB<sub>4</sub> in terms of causing neutrophil chemotaxis and release of lysosomal enzymes [199]. Leukotrienes have been shown to be released from allergen-challenged human lung and to be present in sputum and blood from patients with asthma [200–202].

#### Platelet-activating factor

PAF (1-O-alkyl-2-acetyl-*n*-glyceryl-3-phosphorylcholine also known as PAF-acether or AGEPC) is a lipid substance derived from phospholipids in a large number of cells, including basophils, neutrophils, mast cells, eosinophils, macrophages and platelets [203]. Its actions include aggre-

gation of platelets, induction of lysosomal enzyme and oxygen free radical release from neutrophils and macrophages, and bronchoconstriction and pulmonary oedema. These latter effects may well be secondary to the release of other lipid mediators from cells stimulated by PAF. It is of interest also that it is able to produce both immediate and delayed local reactions when injected into the skin [204].

#### Kinins

Kinins are polypeptides generated in plasma from kininogen precursors with molecular masses of about 200 and 500 kDa. The enzymes responsible are called kallikreins, which in turn are derived from prekallikreins by the action of activated Hageman factor. While this process may take place wholly within the plasma, there is evidence that

Fig. 34.14 Biosynthesis of some of the leukotrienes.

mast cells may produce a kallikrein-like substance [205]. The best-known kinin is bradykinin, a nonapeptide to which asthmatic airways are hypersensitive and which has been found in the skin reactions of atopic subjects [206]. It has no action on normal airways, and it has been

suggested that it may act via a local axon reflex, its release in airways stimulating exposed non-myelinated afferent nerve endings and causing release of sensory neuropeptides [207,208]. These in turn may cause bronchoconstriction, mucosal oedema and hypersecretion of mucus.

### Neural mechanisms

The allergic or immunological model of asthma discussed above provides the best-understood key to the mechanisms of the disease. However, it is plain that allergic sensitization is of little or no importance in a great number of people with asthma. Moreover, studies of mediators have so far been unable to demonstrate convincing qualitative differences between people with asthma and those without, except that patients with asthma tend to show increased susceptibility to their actions. Thus it is necessary to search elsewhere for an understanding of the disease. Two observations in particular have led to an interest being taken in neural mechanisms: first, patients with asthma usually show non-specific bronchoconstrictor responses to a wide variety of non-immunological stimuli such as infection or inhalation of irritants; and, second, psychological stress may lead to exacerbations of the disease. Even more importantly, from a practical point of view, the first-line drugs used in asthma are most frequently those that act upon autonomic nervous control of the bronchi.

Three components of the autonomic nervous system play a part in control of the airways and their secretions [209]: the parasympathetic system via the vagus; the sympathetic system via its hormonal control of cyclic AMP levels; and the peptidergic or non-adrenergic non-cholinergic (NANC) system.

### Parasympathetic control

The vagus nerve includes afferent fibres from sensory receptors in the bronchial epithelium. It is thought, largely on the basis of studies on animals, that stimulation of these receptors by irritants can initiate a reflex impulse along vagal efferents that causes release of acetylcholine and bronchoconstriction [210,211]. Bronchial glands are also under parasympathetic control, and vagal stimulation can also lead to secretion of mucus [212]. The vagal efferent nerves end in ganglia close to bronchial smooth muscle in the posterior walls of the larger airways. The postsynaptic fibres are short and connect with muscle and glands. Vesicles containing norepinephrine (noradrenaline) have been found in the parasympathetic ganglia, suggesting that the sympathetic system may have a modulatory effect on the parasympathetic [213].

In terms of relevance to asthma, parasympathomimetic drugs induce bronchial constriction in patients in much the same way as histamine [214]. Antiparasympathetic

drugs cause bronchodilatation in normal subjects and in patients with asthma [215,216]. In high doses they usually block the bronchoconstrictor response to exercise [149]. Finally, vagal receptors may be stimulated by a number of inflammatory mediators, including bradykinin and histamine [217–219], and this may explain in part the effects of respiratory infections in provoking asthmatic symptoms [220].

### Sympathetic control

The lung receives sympathetic innervation mainly via the stellate ganglion [221]. The postsynaptic nerves supply bronchial vessels but not smooth muscle. Nevertheless, bronchial tone is influenced to a major degree by the sympathetic system,  $\beta$ -receptor agonists causing bronchial relaxation that is antagonized by  $\beta$  blockers. Other studies have demonstrated  $\beta$  receptors on smooth muscle, mast cells and bronchial glands that are presumably stimulated by circulating catecholamines [222,223].

The  $\beta$  receptors exist on the surface of cell membranes, though they should not be regarded as unchanging structures because their numbers may vary from time to time in response to external stimuli. The receptor receives a hormone that has a steric configuration complementary to its own, the binding of hormone to receptor initiating a chain of events that leads to the cell producing its effect. The first step is conversion, in the cell membrane, of guanine nucleotide regulatory protein into its active state, when it combines with the hormone–receptor complex. This leads to activation of adenylate cyclase that catalyses the conversion of ATP to cyclic AMP, the so-called second messenger, which in turn activates the particular cell's specific protein kinases. Cyclic AMP is metabolized by phosphodiesterase to AMP. The actions of the protein kinases depend on the cell; in smooth muscle they phosphorylate myosin light chain kinase and reduce actin–myosin coupling in order to produce relaxation. The release of preformed mediators from mast cells also appears to be under the control of cyclic AMP, reduced levels being involved in the process of degranulation. The relevance of  $\beta$ -receptor mechanisms to clinical asthma is clear from the effects of sympathetic agonist and antagonist drugs. However, study of these mechanisms has pointed to something more fundamental to the understanding of the disease [221]. It has been known for many years that asthmatic subjects may show diminished responsiveness to adrenergic stimulation, in terms of a rise in blood sugar, free fatty acids and levels of cyclic AMP in blood and urine. Much evidence has now accumulated to support the hypothesis that subjects with asthma have a relative reduction of  $\beta$  receptors and a reciprocal increase in excitatory  $\alpha$  receptors. Such differences may be related to genetic factors or may be acquired as a result of allergic, infective or possibly autoimmune factors.

### Peptidergic control

The NANC nervous system was originally described in the gut. Fibres of this system run with the vagus and supply postganglionic fibres to bronchial muscle, glands and vessels [224–226]. Two neuroendocrine peptides in particular have been demonstrated in human sensory airway nerves, substance P and neurokinin A. Activation of these nerves by such stimuli as mechanical or chemical irritation may lead to a form of neurogenic inflammation, with bronchoconstriction, extravasation of protein-rich fluid and vasodilatation in the airways. There is also evidence that release of these transmitter substances may influence the attraction of inflammatory cells to the site. Both substance P and neurokinin A administered by inhalation cause bronchoconstriction; this effect is reduced by prior inhalation of cromoglicate and amplified if the action of neutral endopeptidase, the enzyme responsible for their natural breakdown, is blocked. It seems reasonable to propose that neural mechanisms such as these play an important part in the initiation of non-immunological asthma, such as occurs after viral infection or exposure to irritant substances, the so-called reactive airways dysfunction syndrome.

### Bronchial muscle

The contractile mechanism of bronchial smooth muscle is due to the ability of the proteins actin and myosin to interact and to slide over one another [227,228]. In outline, myosin is composed of a pair of filamentous heavy chains coiled around each other, ending in a globular structure to which are attached two pairs of light chains. The globular head is attached by a cross-bridging mechanism to actin, which is also a filamentous protein consisting of two intertwined polymers. These in turn are wrapped round two intertwined molecules of tropomyosin. Contraction takes place by detachment of the globular part of the myosin from the actin and reattachment further along the structure, the energy for the reaction being derived from breakdown of ATP by activated myosin ATPase. The sequence of events leading to activation of myosin ATPase is as follows [228,230]. A fundamental requirement appears to be an approximately 10-fold increase in intracellular calcium ion concentration. Normally the concentration of calcium in smooth muscle cells is about 10 000 times less than that in extracellular fluid, the differential being maintained by the cell membrane and an active energy-dependent removal mechanism whereby it is exchanged for sodium. However, the cell membrane may allow calcium to enter when channels are opened, either via the actions of drugs or hormones on receptors or by changes in the transmembrane potential difference. Influxing calcium combines with the protein calmodulin and this combination activates myosin light chain kinase. The acti-

vated enzyme then phosphorylates one of the pairs of myosin light chains on the globular part of the molecule, leading in turn to activation of myosin ATPase and contraction. Another calcium-dependent pathway has also been described in the activation of myosin ATPase; an enzyme present in the cell membrane called protein kinase C alters the sensitivities of actin and myosin to calcium. The protein kinase C is in turn activated by calcium flux across the membrane.

Thus calcium is thought to play a central role in the contraction of smooth muscle. Yet calcium channel blocking drugs have proved of little therapeutic value in asthma, in contrast to  $\beta$ -sympathomimetic drugs that act to increase levels of cyclic AMP in the smooth muscle cell. The part played by cyclic AMP is not clear, although rises in its concentration have a wide range of effects including activation of various protein kinases (that may inhibit calcium transfer and activation of protein kinase C) and by increasing the inward flow of sodium in exchange for calcium. The lack of efficacy of calcium-blocking drugs may be explained partly by their inability to block the receptor-dependent channels. Despite the well-recognized bronchial hyperreactivity of asthmatic airways, no clear picture has yet emerged of the biochemical correlates of this process. Although it is tempting to believe that a fundamental abnormality may be present in the regulation of intracellular calcium metabolism, the evidence seems to indicate that bronchial reactivity *in vivo* does not relate to altered mechanical properties and responses of the excised muscle *in vitro* [231]. However, there is some evidence that asthmatic airway smooth muscle does have altered mechanical properties [232].

## Genetic factors

The frequent clinical observation that asthma runs in families has been supported by many more formal investigations [233–237]. There is a greater concordance for asthma in monozygotic than dizygotic twin pairs. The risk of having an asthmatic child is greater if both parents have the disease than if one does, and greater if one has it than if neither does. However, study of the genetics of asthma is made particularly complex by the absence of agreement on definition of the phenotype, which could for example include atopy, bronchial hyperresponsiveness and any number of consequences due to genetic polymorphisms involving individual cytokines and cell receptors [238]. Recent studies, in which atopy has been defined in terms of one or more positive skin tests, positive specific IgE or raised total IgE levels, have produced somewhat contradictory results. The original findings suggestive of autosomal dominant inheritance based on a gene on chromosome 11q13 have been supported by work that has shown an association between atopy and an amino acid substitution in the  $\beta$  subunit of the receptor for IgE, the

gene for which is also located on chromosome 11q13 [239–241]. This receptor is responsible for the changes in calcium flux leading to mediator release. However, studies of other family groups have failed to replicate these findings and it seems very likely that different genetic polymorphisms in different populations can produce what to the clinician appears to be the same phenotype [238]. Other linkages have been demonstrated between chromosome 14, the T-cell receptor and specific IgE reactions to major allergens [242], and between chromosome 5q and a cluster of cytokines including IL-3, IL-4 and IL-5 [243]. The complexity of the multiple mechanisms and network of cells, cytokines and chemokines involved in asthma, the differences in the clinical manifestations of the disease and the now very obvious increasing prevalence of atopic diseases, and thus the dominance of environmental factors in their expression, make one wonder whether the current emphasis on genetic research is likely to pay the rich dividends anticipated by some of the pharmaceutical companies investing in it. While it will surely lead to new and possibly better drugs, it may be that a greater research emphasis on factors influencing the expression of whatever genes are involved in determining atopy and bronchial reactivity may produce greater dividends in terms of prevention.

## Why has asthma increased?

One of the greatest enigmas in the study of asthma arises from the repeated observation that the disease has become more common in prosperous societies. This has been demonstrated in repeated cross-sectional studies in the same place, in studies of populations that have migrated from poorer to richer societies, and in studies of people of similar racial background living traditional or more sophisticated lifestyles. The increase in asthma appears to be paralleled by increases in atopy and the other allergic diseases, hay fever and eczema. These observations provide an important challenge in understanding and reversing the environmental factors that lie behind them.

Early attempts to attribute these changes to an increasingly toxic environment, whether due to maternal smoking, increases in exposure to mites and other allergens or to air pollution, are likely to provide at best a very partial explanation [244]. The changes in prevalence of atopy seem to be occurring very early in infancy, and possible or recorded changes in these toxic factors are unlikely to be large enough to have produced the observed effects. For example in the UK, smoking prevalence in women of child-bearing age has decreased over the relevant period, pet ownership has not increased and urban particulate air pollution has decreased substantially. If the increase in asthma was due to a large increase in exposure to mites, an unlikely event given the high exposures in bedclothes almost universal 30 years ago [245], it is strange that hay

fever has increased despite no change in grass pollen levels [246]. Thus it seems much more likely that the increase in prevalence is primarily a consequence of an increase in population susceptibility (Fig. 34.15).

Two hypothetical but plausible means by which population susceptibility could have increased suggest themselves. First, the diet of the population could have altered in such a way as to decrease resistance to allergens [244,247]. Secondly, falling rates of infection in infants could have removed a stimulus towards development of the anti-infection Th1 phenotype, leaving a population with an increased proportion of the atopic Th2 phenotype [248,249]. There is evidence that newborn babies destined to become atopic already show decreased concentrations of IFN- $\gamma$ , a cytokine associated with the Th1 phenotype, and evidence of *in utero* sensitization to allergen in their cord blood [250], suggesting that the key determinant of atopic and therefore likely asthmatic status in childhood may occur before birth. Other evidence, from studies of populations, has suggested that early childhood infections may protect against later atopy, though not asthma. Children in Guinea-Bissau who had severe measles were less likely to become atopic, while the same was true of children in Japan who were tuberculin positive and of Italian military recruits who had serological evidence of past hepatitis A infection [251–253]. In contrast, except for measles which had a weak effect, the common childhood infections in Aberdeen schoolchildren did not protect from (but rather in general appeared to increase the risk of) later asthma [254]. All these studies have pointed to an intriguing effect of family size on risk of atopy, in that children in larger families were relatively protected, an observation not wholly explained by infection but which also may point to some subtle intrauterine effect.

It is becoming apparent that the change in asthma prevalence is associated with a rising standard of living rather than with westernization *per se*. Thus children in the

same country, be it Ethiopia or Saudi Arabia, neither of which can be regarded as westernized, show a much greater prevalence of asthma and allergic symptoms among the wealthier urban than among the poorer rural children [255,256], whereas urban–rural differences do not exist in countries that are relatively uniformly wealthy. Some factor associated with increased prosperity, be it a different diet, reduced opportunity for childhood infection, increased use of immunization or a combination, must be responsible. The authors favour a dietary hypothesis, since increasing prosperity is accompanied by the consumption of less fruit and vegetables and a different pattern of fat intake. A lowered consumption of vitamins C and E, coupled with changes from  $\omega$ -3 to  $\omega$ -6 fatty acids in the diet of the pregnant woman, could theoretically influence T-lymphocyte differentiation in the unborn child and tip the balance towards a predominantly Th2 phenotype persisting at birth when the child first meets inhaled allergens [247,257] (Fig. 34.16). At this stage a lowered antioxidant level in the child could further reduce its resistance to substances capable of causing bronchial inflammation. As childhood progresses, it is conceivable that immunization and freedom from, say, intestinal infections reinforce rather than switch the Th2 phenotype, so that by the age of 12, the stage at which most of the epidemiological studies have been done, atopic symptoms have become commonplace. It must be stressed that this hypothesis remains unproven but forms a useful template for further research and may point the way to future prevention.

## Clinical features

### Taking the history

The diagnosis of asthma is usually made as a result of careful history-taking, supported by a few tests or by a trial of therapy. In most cases a properly taken history gives the diagnosis. The history should discover the presenting symptoms, their periodicity and evolution and factors related to their variability. In particular, factors provoking attacks should be sought. An assessment of the patient's level of disablement should be made, not forgetting that disturbed nights lead to impaired performance in the day. The history should also discover any associated features, such as other atopic disease and drug sensitivity.

### Presentation

Asthma may present at any age, including the extremes of life. The most common presenting symptom is breathlessness usually associated with chest tightness, often coming on in attacks, although in older people it is frequently a chronic symptom. Wheeze is often not the primary complaint and is a term usually put into their mouths by their

**Fig. 34.15** Distribution of susceptibility to asthma in a population showing how a small overall shift can substantially increase the prevalence of overt disease.

**Fig. 34.16** Possible factors influencing susceptibility to asthma. The undifferentiated T lymphocyte may become either the antimicrobial Th1 cell, producing interferon  $\gamma$  under the stimulus of certain infections, or the Th2 cell, producing interleukin 4 and leading to allergic inflammation through the production of IgE

by B cells. Antioxidants might protect directly against allergic inflammation and vitamins E and C may together downregulate Th2 differentiation. The balance of fatty acids in the diet may also affect T-cell differentiation.

doctors, patients often preferring to refer to tightness in the chest. A large minority of patients present with cough, which may be the only symptom, especially in children. When cough is troublesome, bilateral aches or pains in the chest are common. In some patients cough is productive of small amounts of sticky sputum, although it is rare for profuse or frothy sputum to be produced. Sputum is usually described as being white or clear; sometimes more solid or greenish streaks are noticed in it.

Of particular importance in making the diagnosis of asthma is the periodicity of symptoms. In children and young adults the usual complaint is of episodes of cough, wheeze and breathlessness. These characteristically occur shortly after exertion and at night. Persistent dry cough may be the only symptom. Exercise-induced symptoms occur after several minutes of usually unaccustomed exertion, increase in severity over a minute or two and wane over about half an hour, though mild attacks may last only a few minutes. The patient may or may not notice wheeze. Nocturnal symptoms typically disturb sleep in the small hours of the morning. Many patients feel the need to get up and out of bed to go to a window for air. Others make themselves a cup of tea after being awakened by symptoms, an almost pathognomonic symptom. Attacks also vary greatly in severity, from a mild episode of cough lasting a few minutes to a night repeatedly disturbed by

frightening breathlessness, wheeze, chest tightness and cough. In general, the frequency and severity of nocturnal episodes may be taken to be a useful guide to the current severity of asthma. If a patient is seen during the day and is clinically reasonably well but describes distressing nocturnal symptoms, more weight should be put on the history than on the immediate apparent good health when assessing the severity of asthma and the planning of its treatment. Moreover, the time at which the attacks occur is also a guide to severity. Most patients with mild to moderate untreated asthma wake in the morning at their normal time with a tight chest and some wheeze, or a dry cough. Measurement of peak flow rates, which are characteristically lower in the mornings in asthma, has led to this being described as the 'morning dip'. As asthma, and presumably airways hyperreactivity, becomes more severe, symptoms occur earlier and disturb sleep, until in some cases the patient barely sleeps at all or is woken repeatedly through the night by breathlessness, wheeze and cough. Nocturnal asthmatic symptoms are discussed further in the next section, but it should be pointed out that they are a feature of asthma of all types at all ages and not simply related to house-dust mite hypersensitivity.

Particular attention should be paid to factors provoking attacks. Exercise has been mentioned; almost as frequently, patients comment on attacks following 'colds'.

Care should be taken to distinguish genuine viral infections, with fever and malaise, from rhinitis. While the latter is common in asthmatics and frequently accompanies attacks, the former commonly provoke them. Often a bad upper respiratory tract infection leads to cough and wheeziness that persist, sometimes for weeks, and do not respond to the antibiotic therapy which is often unnecessarily given in repeated courses. Such patients do not have persistent bronchial infection despite their cough and sputum. Their sputum, if apparently purulent initially, rapidly becomes mucoid and sticky and they usually have troublesome nocturnal symptoms. Sputum may occasionally appear to be purulent in asthmatics; this green colour is due to peroxidase, which is released from eosinophils as well as neutrophils. Symptoms are due to bronchial hyperreactivity following the infection and respond to anti-inflammatory therapy but not antibiotics. Other common factors that may provoke asthma are exposure to allergens, cold air, chemicals in the workplace, drugs and emotional upsets. These are discussed in subsequent sections.

In terms of making a diagnosis from the history, the most difficult presentation is in middle-aged and elderly people. While most such patients present with typical symptoms, some present with progressively increasing cough and dyspnoea, without the characteristic day-to-day variability. Nevertheless, they usually admit to nocturnal symptoms and these are frequently assumed to be manifestations of cardiac disease. One important feature of the history should always be sought, namely the relationship of the start of symptoms to cigarette smoking. Anyone who starts wheezy breathlessness and cough some weeks or months after stopping smoking is likely to have asthma. It is a commonplace observation that such patients complain that their chest has never been right since they stopped, although a careful history reveals that the symptoms usually started some time after cessation. If symptoms were present when the patient stopped smoking, a diagnosis of smoking-induced chronic obstructive airways disease is more likely. In terms of management this distinction is less important than it appears, since all such patients developing airflow obstruction are treated similarly initially in order to assess their response and many initially categorized as having smoking-induced disease nevertheless respond at least partially to such treatment. This is discussed further below.

### Provoking factors

#### Allergy

The possible mechanisms whereby allergy provokes asthma have been discussed. Over 90% of childhood asthmatics are atopic, though this proportion falls among

adults to some 50% [258–260]. In most atopic subjects allergy is only one of many factors, including exercise, infection and emotional upsets, that provokes attacks. Nevertheless it is always desirable to consider possible allergic factors and to try to eliminate important ones wherever possible.

The chest physician confronted by an asthmatic patient is faced with a daunting task in investigating allergic factors. The most important guide to the relevance of these comes from the history. Allergens may be encountered in the general, the domestic and the occupational environment, and timing of the symptoms may give an important clue. Seasonal variation suggests allergy to pollens or spores in the air. Symptoms in the working week and improvement when away from work throw suspicion on occupational factors. Associated rhinitis or conjunctivitis is a useful pointer to an allergen; house dust, animals and pollen rarely cause attacks of asthma without some nasal manifestations. Allergy to food or food additives is usually very difficult to detect from the history, although many such patients find that certain foods or drinks make their symptoms worse. The following sections discuss the main allergens with the exception of those encountered in an occupational setting, which are dealt with separately.

#### House dust and mites

Most atopic asthmatics report symptoms on exposure to house dust, usually when making beds and when dusting. Exposure while in bed may cause perennial rhinitis and nocturnal attacks of asthma, although this is by no means the only cause of asthma during the night. The major allergen in house dust was shown in the 1960s to be due to mites [261–263], though an occasional patient shows sensitivity to house dust alone and not to the mites in it. At least in temperate climates, *Dermatophagoides pteronyssinus* (Fig. 34.17) is the most prevalent of the mites found in house dust; others such as *Euroglyphus maynei*, *Chyletus* spp., *Glycyphagus* spp. and *Tyrophagus* spp. may also be found in small numbers [245]. *Dermatophagoides farinae* is rare in the European house habitat and is a more common organism in the USA; it should be noted that different species become dominant in different environments such as holiday caravans or stored grain. *D. pteronyssinus* lives mainly on skin scales and the fungi that feed on them [264]; it prefers a dark, warm and humid environment, around 25°C and 80% relative humidity, being in temperature and fluid equilibrium with its environment. These conditions are ideally provided by a bed. It breeds rapidly, the female producing up to 300 eggs in its short life. It is easily found in the small collections of dust round buttons and piping on mattresses and in blankets, pillows and other bedclothes, as well as in dust accumulated in curtains, carpets and other household sources. The highest

Fig. 34.17 Scanning electron micrograph of *Dermatophagoides pteronyssinus*.

concentrations, up to 13 000/g of dust in one study, are found in mattresses [245], although large numbers (up to 100 000/m<sup>2</sup>) may be present in a carpet. Interestingly, hospital mattresses are usually free of mites, indicating that regular disturbance of the colony by changing beds and exposing the mattresses to light makes the microenvironment unsuitable for their survival [245,265]. Conversely, low standards of domestic hygiene encourage house-dust mite colonies to thrive. The main allergen from mites seems to be excreted in the 20 or so faecal pellets each mite produces daily [266]. The faecal pellets are some 10–40 µm in diameter and thus easily become briefly airborne and inhaled into the nose and conducting airways [267,268]. Once inhaled and deposited onto a moist mucous membrane, the soluble allergens leach out of the faecal pellet. The main allergens have been characterized and are known as *Der pI*, II, III and IV indicating the order in which they were found [269]. Monoclonal antibodies to these allergens allow their quantification in air, dust and other media. *Der pI* is a cysteine protease with a molecular mass of about 25 kDa, while *Der pIII* is a trypsin with a molecular mass of about 30 kDa; these are the two allergens to which almost all mite-sensitive subjects react. *Der pII* is probably unimportant as an allergen and *Der pIV*, an amylase with a molecular mass of about 60 kDa, sensitizes a minority of subjects. The fact that these allergens, derived as they are from the gut of mites, are enzymes is interesting in terms of their ability to obtain access to sub-mucosal lymphocytes in the respiratory tract.

Other allergens in house dust include animal dander and feathers. Hair itself is not allergenic. The presence of an animal in the house ensures that it makes some contribution to the dust's antigenicity, though the main threat is usually posed by more direct contact between patient and pet (see below). Feather allergy seems to be related to a

mixture of proteins from keratin, although apparent allergy to feathers in pillows or downies may rather be related to their mite content.

#### Pollens

Plant pollen grains are major causes of seasonal rhinitis (hay fever) and in such patients commonly provoke asthmatic symptoms as well. Allergy to pollens causes a distinctive illness in that the rhinitis is usually associated also with itchy conjunctivitis and lacrimation, and the symptoms have a distinctly seasonal pattern. Pollination of plants occurs at the same season each year but the amount of pollen that becomes airborne depends on the plant's natural method of pollination (via wind, water or insects) and the climatic conditions [270,271]. Pollen allergens therefore differ considerably between different regions of the world and from time to time in the same region. In Europe, the most frequent allergens are grass pollens and these cause symptoms from about April to August; pollination is promoted by wind and sunshine and occurs earlier in more southern latitudes. Counts of grass pollen may rise as high as 1000/m<sup>3</sup> on a hot summer's day. Symptoms typically start in the mid-morning and may persist through the next night.

Grass pollens are 30–50 µm in diameter and soluble antigens with molecular masses of 30–40 kDa are found on their surface. Osmotic rupture of the grain may cause release of starch granules bearing these antigens; this has been proposed as a mechanism whereby heavy rain during a thunderstorm may be responsible for epidemic outbreaks of asthma [272,273]. There is considerable cross-reactivity between pollens from different species of grass [274]. Certain weeds, generally of the family Compositae, may also be important sources of allergen. As with mites,

the major allergens are denoted by letters and numbers indicating the source species and the order in which they were characterized. In North America in particular, especially in agricultural areas of the central and eastern regions, ragweed (*Ambrosia* sp.) is a major source of allergen [275–277]. It pollinates in August and September. Mid and late summer allergic symptoms may be due to nettle or mugwort pollen, while symptoms in the spring may be due to pollen from trees such as alder, elm, ash, birch, beech or oak, all of which pollinate between February and May in temperate climates. The seasons of some of the important pollen allergens in the UK are shown in Fig. 34.18.

Seasonal asthma always suggests an airborne biological allergen. However, it should be clear that this depends on the local flora and a knowledge of this is essential for making a diagnosis. Pollens may travel hundreds of miles in the air, although high concentrations are obviously only likely to occur close to a source. The introduction of new species of plant into a region may be followed by important epidemics of respiratory symptoms, as occurred in Kuwait when decorative trees of the species *Prosopis* were planted in previously desert areas [278]. The widespread cultivation of oilseed rape in the European Community has given rise to fears that it may be an important new cause of epidemic asthma; however, since it produces large grains and is primarily pollinated by insects, this seems not to be the case [279,280]. Nevertheless, it does occasionally sensitize people working with it in agricultural laboratories and therefore has allergenic potential with respect to heavily exposed atopic individuals.

### Fungal spores

Like plant pollens, fungal spores may also become airborne and cause sensitization. Fungal spores are usually smaller than pollen, being about 5–20µm in diameter [270,271]. Each species has its distinctive shape, varying from roughly spherical to torpedo-like. They usually appear to cause asthmatic symptoms without rhinitis. Although the total numbers of spores in the air may be exceedingly large, because of their smaller size the antigenic load is usually much less than that from grass pollen and this probably explains why fungal allergy is generally less of a problem than pollen allergy. Nevertheless, some patients do become sensitized and also develop seasonal symptoms in relation to the sporing season of the organism [281,282] (Fig. 34.19). Most fungi are either parasites or saprophytes of plants or live on dead organic matter. Their classification and nomenclature are discussed in Chapter 21. Different fungi predominate in different macroclimates and microclimates, according to the availability of suitable substrates. In Britain and other temperate climates, *Cladosporium* spp., basidiomycetes (including smuts and rusts), ascospores, *Sporobolomyces* spp., *Alternaria* spp., *Fusarium* spp. and *Penicillium* spp. are the most common spores in the air generally. However, local factors such as fields of cereals, compost heaps or rotting wood may cause very high local concentrations of other organisms. *Aspergillus fumigatus* may sensitize people working with compost, farmers may develop asthma in relation to large numbers of spores liberated at harvest time, and people living in damp mouldy houses or exposed to dry rot may develop asthma related to organ-

**Fig. 34.18** A guide to the pollen season of common British plants. This varies somewhat according to latitude and weather.

Fig. 34.19 A guide to the spore season of common British fungi. This varies according to the weather and local availability of substrates.

isms such as *Aspergillus niger*, *Merulius lacrimans* or *Penicillium* spp. It is of interest that *Aspergillus* spp. are not among the most frequent fungi in the air spora and yet they are probably the most troublesome species of fungus in terms of sensitization and disease; this is discussed separately in the section on bronchopulmonary aspergillosis. It has been postulated that the presence of activated epithelial cells and the exposure of basement membrane that occurs in asthma, together with oxidant stress, may facilitate the colonization of the asthmatic lung by *A. fumigatus* [283]. The incidence of positive skin reactions to *A. fumigatus* in unselected atopic asthmatics ranges from 10 to 20% [258]. A prerequisite for the development of aspergillar hypersensitivity is repeated exposure to the *Aspergillus* antigen [284]. Two distinct antigens, *Asp fl* (an 18-kDa protein) and a 48-kDa protein, have been identified as important causes of IgE antibody responses [285].

In clinical terms, fungal allergy (apart from aspergillosis) is probably not a frequent cause of troublesome symptoms [286]. However, there is increasing evidence that damp housing, which predisposes to the growth of moulds, is associated with a higher prevalence of asthma [287–290], although it is often difficult to separate this from the effects of the house-dust mite which also thrives in some damp houses [290]. Suspicion should be aroused in seasonal asthma without rhinitis [282] and when symptoms point to some specific site of asthma provocation, such as the house or workplace. The use of fungi in biotechnology is another area where sensitization may occur [291]. Fungal-induced asthmatic reactions in general have been well reviewed [292].

#### Animals

Up to 25% of atopic asthmatics show skin sensitivity to an animal [293]. Sensitization usually arises as a result of regular contact, and therefore is normally to a household

pet or farm animals. Cats, dogs, horses and guinea-pigs are those most commonly encountered, though rabbits, white mice and even rats and ferrets are kept as house pets. Occupational sensitization to laboratory animals is a widespread problem. Birds, such as budgerigars, occasionally provoke asthma, although allergic alveolitis is a more common problem. All asthmatic patients should be asked about pets and animal contact. If sensitization is of clinical significance, the patient is likely to have noticed rhinitis and conjunctivitis as well as wheeze on contact with the animal. The sensitization is to animal proteins on particles derived from urine or saliva. In occupational cases, animal allergy may be the only cause of the asthma, which often remits when exposure ceases; occasionally this may be the case with domestic exposure. Allergy to the major cat allergen, *Fel dI*, is much more of a problem than allergies to other domestic pets. Cat-owning asthmatics with proven allergy to their pets rarely (and understandably) take medical advice about removal of the animal from their households [294], and there is evidence to suggest that asthmatics with cats require higher doses of inhaled corticosteroid therapy to control their symptoms than patients with dogs and other pets [295]. It has been suggested that in some countries, such as Sweden, cat allergy is the most important problem in childhood asthma [296].

Occasionally arthropods other than mites may cause asthma, and in some parts of the world cockroaches rather than mites are the main domestic allergen. Research workers studying locusts have been reported to develop symptoms, as have people exposed to various flies and to cockroaches [297–300]. Epidemic asthma has been reported in the Sudan due to a midge [301].

#### Food, drink and drugs

Atopic asthmatics may occasionally notice that their

symptoms are provoked by certain foods or drinks and it is worth asking all asthmatic patients whether they have noticed such an association. In the authors' experience it occurs in less than 10% of patients. The foods most frequently suspected are milk, eggs, fish, cereals, nuts and chocolates, but very many others have been described [302,303]. Meats containing antibiotics fed to animals or tenderized with enzymes are recognized as occasional causes. It is thought that sensitization occurs as a result of pinocytosis of antigenic protein molecules by intestinal mucosal cells (perhaps in the Peyer's patches) and induction of an IgE antibody response [304]. Subsequent entry of antigen into the bloodstream provokes an IgE-mediated reaction. Some of these patients notice gastrointestinal symptoms as well as wheeze; indeed such symptoms alone are a more frequent consequence of food allergy than is asthma. Anaphylaxis is a serious consequence of food allergy and appears to be occurring more frequently than before; peanuts, widely used in a large number of prepared foods, are most commonly to blame. Such patients need to exclude the offending substance absolutely from their diet and to be instructed in use of emergency epinephrine (adrenaline) injections.

Food may also provoke asthma via mechanisms that may not be related to IgE-mediated allergy. Preservatives such as benzoates, sodium nitrite and sodium metabisulphite, synthetic antioxidants, dyes such as tartrazine, and flavourings may be found in many foods and may provoke asthma. Red wines contain a number of congeners that give them their distinctive flavours but which also may provoke attacks of asthma, perhaps by a direct effect on mast cells causing liberation of mediators [305,306]. In general, however, alcohol itself is a mild bronchodilator [307,308]. It has been postulated that asthma associated with chewing betel-nut is chemically mediated by cholinergic stimulation [309].

An observation of some interest was that regional variations in asthma mortality in England and Wales correlated with dietary intake of sodium [310]. It has also been shown that bronchial reactivity to histamine is related to 24-h urinary sodium excretion [311], and it is possible that changes in dietary salt intake could alter the activity of the bronchial smooth muscle cellular sodium pump, which may be relevant to bronchial reactivity [312]. However, in a study of Montreal schoolchildren no association was found between asthma or exercise-induced bronchospasm and dietary salt intake, although bronchial responsiveness to methacholine did appear to increase with greater salt intake [313]. Absence of a relationship with peak flows and and peak flow variability has been reported [314], as has presence of a relationship to bronchial reactivity in some populations and not in others [315]. Yet other studies have linked increasing dietary salt intake with worsening asthma symptoms and increased bronchodilator use [316–318]. These discrepancies suggest

that the effect of salt intake is unlikely to be an important determinant of asthma [315], and it may be that it is a marker of an otherwise unsatisfactory diet [319].

Recently it has been suggested that omissions from, or changes in, the pattern of diet rather than allergenic additions may have played some part in the increase in allergic diseases in developed countries (see p. 940) [244]. Although diet may be responsible for some of the differences in the prevalence rates of asthma between countries, the extent of the effect is not known [56]. Breast-feeding is often cited as a protective factor, although the evidence is contradictory. A regular fish diet appears to reduce the risk of airway hyperresponsiveness in Australian children [257] and there are theoretical reasons why fish oils might alter the course of asthma via metabolites produced from arachidonic acid. Recently it has been postulated that dietary polyunsaturated fats, notably  $\omega$ -6 fatty acids such as linoleic acid, may influence the development of allergic sensitization by increasing the formation of PGE<sub>2</sub>, promoting Th2 lymphocyte responses and IgE generation [247]. Also dietary changes leading to a decrease in the intake of antioxidants such as vitamins C, E and  $\beta$ -carotene have been suggested as a possible cause of alterations in population susceptibility to atopic disorders [244], and some evidence now supports the concept that a diet high in fats and low in vitamins C and E is an important risk factor for adult-onset asthma and bronchial hyperreactivity [320,321]. Vitamin E may also be immunomodulatory and able to influence T-helper cell development in the direction of Th1, while vitamin C acts to reduce oxidized vitamin E radical and thus regenerate the active vitamin. It now seems likely that diet will prove to play a role in the development of susceptibility to allergens, although the magnitude of this effect has yet to be determined.

Drugs are an important but occasional cause of asthmatic attacks. Aspirin and other non-steroidal anti-inflammatory drugs are the most frequent offenders, followed closely by  $\beta$  blockers. The drugs and mechanisms are discussed in more detail in Chapter 55. It should be noted that aspirin sensitivity occurs particularly in non-atopic adult asthmatics, the combination of asthma, anti-inflammatory drug sensitivity and nasal polyposis constituting a well-defined syndrome. Tartrazine, a well-recognized chemical cause of asthma, may also be present in many drugs as well as in foods [322].

### *Infection*

Viral infections are one of the most common and important triggers of asthma exacerbations, especially in atopic infants [323]. There is some evidence that viral infections in childhood may predispose to the development of asthma and bronchial hyperreactivity in later life [324–326]. Both respiratory syncytial virus infection and croup may be followed by persistent wheezing and hyper-

reactivity, and it has been suggested that such infections may also precede sensitization to common allergens in children of atopic parents [327–330]. The other view is that genetic predisposition is required to allow this to happen, and only transient damage occurs in previously normal individuals [331]. Asthma and acute viral infections are among the commonest of respiratory afflictions. There is a strong association between viral respiratory infections and both the onset and exacerbation of asthma, and the nature of the association is an important area for future research. Recent information suggests that this link may not be wholly accidental but may reflect specific interactions of viral proteins with the host immune system [332].

From the point of view of the chest physician, viral infections in adults are frequently followed by protracted cough and wheeze indistinguishable from asthma [333,334]. The viruses usually responsible are influenza, rhinovirus and respiratory syncytial virus, together with the bacterium *Mycoplasma pneumoniae*. Asthmatic patients with these infections usually suffer attacks of wheeze lasting several weeks. Even non-asthmatic subjects can be shown to have a prolonged period of hyperreactivity, probably related to the mucosal epithelial damage and irritation of vagal receptors [220,335,336]. In contrast, infection with pyogenic bacteria rarely causes acute exacerbations of asthma, though such infections may occasionally be superimposed on a previous viral infection.

### *Air pollution*

Certain air pollutants, notably sulphur dioxide (SO<sub>2</sub>), ozone and nitrogen dioxide (NO<sub>2</sub>), are able to cause bronchoconstriction when inhaled at high concentrations, although the concentrations that cause this effect are rarely reached in outdoor air in the West nowadays. Nevertheless, epidemiological studies have shown an association between episodes of pollution, primarily with particles and ozone, and exacerbations of asthma [337]. Some reports from the UK indicate that currently encountered levels of air pollution may have measurable but small effects on hospital admissions for asthma and on the lung function of adult asthmatics [338,339]. Studies in the USA and Canada have also shown positive correlations between asthma admissions and ozone, SO<sub>2</sub> and sulphates [340,341], and fluctuations in the concentrations of SO<sub>2</sub> and ozone have been associated with patterns of attendance at casualty departments for acute wheezy episodes [342]. In children a small but statistically significant adverse effect on lung function has been linked with air-borne respirable particulate matter, measured as PM<sub>10</sub> (particles <10µm in diameter), but not with levels of ozone or NO<sub>2</sub> [343,344].

Although these studies point towards an interaction of

air pollution and asthma, the results are not entirely consistent, particularly when linking an individual pollutant to asthma. The main problems with these studies have been difficulty in differentiating asthma and other chronic airway disease and in controlling for confounding variables, including geographical variations in weather, other pollutant levels, occupation, lifestyle, smoking habits, infections, allergens, socioeconomic status and healthcare facilities [345]. Air pollution in general has lessened in the UK at a time when asthma and atopic disorders have increased, and there is the well-known paradox that heavily polluted countries have in general more chronic obstructive pulmonary disease (COPD) and less asthma than do less polluted countries. It is highly unlikely therefore that air pollution is responsible for the increased prevalence of childhood asthma, episodic wheezing and hay fever seen over the last two decades [346]. Functional responses of asthmatics to ozone, NO<sub>2</sub> and SO<sub>2</sub> have been extensively evaluated in controlled exposure studies [346,347] and these studies have shown that asthmatics are abnormally sensitive to SO<sub>2</sub> but not to NO<sub>2</sub> or ozone. However, the possibility of some synergistic effects of combinations of ozone, NO<sub>2</sub> and SO<sub>2</sub> cannot be excluded.

Controlled human exposure studies suggest that air pollutants can potentiate inhaled responses to aeroallergens [348–351]. The mechanisms contributing to the potentiation of responses to aeroallergens following exposure to outdoor and indoor air pollutants is not well understood, but could be the result of pollutants causing shedding of the bronchial basal epithelial cells [345], allowing access of antigen to submucosal lymphocytes and possibly exaggerating the immune response by increasing IgE synthesis [352].

There is thus good evidence that air pollution can influence asthma morbidity and mortality in those who have the disease. However, the evidence does not support the view that air pollution could account for the increasing prevalence of asthma, nor does it support the view that chronic exposure to raised levels of ambient air pollutants can trigger asthma in normal healthy individuals [345].

### *Smoking*

The interrelations of smoking, asthma and atopy are ill understood. Smokers appear to be at greater risk of developing asthma and have a higher prevalence of hyperreactivity [353,354] but the role of smoking as an independent cause of asthma has been questioned [355]. In a long-term follow-up study of a childhood cohort, atopy and smoking were two important predictors of adult-onset wheezy illness [356]. It seems likely that smoking is an important risk factor for reversible airflow obstruction in adults, although the very fact that a patient is a smoker inclines doctors towards a diagnosis of COPD rather than asthma, causing unnecessary confusion to epidemiologists.

The role of environmental tobacco smoke as a cause of asthma remains uncertain. Asthma has been associated with tobacco smoke more strongly in young children [357–359] than in school-aged children in whom the evidence is confusing [360–365]. On the other hand, there are many reports of a significantly increased risk of wheeze in school-aged children. While wheeze is often used as a surrogate measure of asthma, different definitions of wheeze have been used in various studies, making comparisons between studies difficult. Another difficulty with these studies is the confounding effect of other factors associated with social class, and it seems to the authors that in general a relatively poor environment in the West, associated with parental smoking, poor housing and a bad diet, combine to increase the risks of wheezy illness in adolescents and adults.

To add further complexity, it has often been observed by clinicians that asthmatic symptoms commence more frequently than would be expected in individuals who have recently stopped smoking; in some of these, symptoms improve if they restart. There may be an immunosuppressant effect of smoke (which could also explain the relative resistance of smokers to the development of allergic alveolitis) and this is an area that requires further research.

### *Psychological factors*

Most patients with asthma acknowledge that exacerbations may be provoked by psychological events, such as shock, bereavement or excitement. However, such factors are rarely the dominant cause of the disease [366,367]. Suggestion (and its extreme form, hypnosis) may have important effects in modifying asthmatic reactions to provoking factors in either direction [368,369], and good doctors make use of this in their management of such patients. In one study hypnosis abolished skin sensitivity, even though the presence of antibody in serum was still demonstrable by the Prausnitz–Kustner reaction [370].

The psychogenic effects on airways reactivity are presumably mediated by the autonomic nervous system, and the effects of suggestion in provoking bronchospasm may be blocked by atropine [371]. Hyperventilation induced by anxiety or laughter may also be responsible for asthmatic reactions.

The severe asthmatic attack may be very frightening, and such patients are understandably anxious. It is important to recognize this and to reassure the patient, while treating the asthma rather than the anxiety with drugs. The parents of an asthmatic child frequently and understandably become anxious and tend to be overprotective towards the child. This also should be recognized by the doctor, and managed by proper care of the child and reassurance of the parents. It is likely that such psychosocial factors in a family contribute to the severity of the asthma,

and they should always be sought for and dealt with as far as possible. Occasionally, psychological illness, family disputes or marital problems may be major factors in the aetiology of intractable asthma and expert psychiatric help may be necessary.

### *Gastro-oesophageal reflux*

It is now well recognized that episodes of gastro-oesophageal reflux may provoke wheeze as well as the more familiar symptoms of heartburn [372,373]. Not all asthmatics respond in this way to reflux, but in those that do a lowered intraoesophageal pH seems to initiate a fall in FEV<sub>1</sub> over about 90 min [374,375]. Acidic drinks, such as colas and fruit juices, and iced water produce similar effects. In some cases where reflux symptoms are troublesome, fundal plication or treatment with an H<sub>2</sub> blocker has also resulted in amelioration of the asthmatic symptoms [376,377]. Gastro-oesophageal reflux is common and enquiry about it should be routine in history-taking in the asthmatic. While it plays no part in the generation of the common nocturnal symptoms in most patients [378], reflux should always be considered as a possible provocative factor in the 'difficult to control' asthmatic [379]. If an asthmatic patient has prominent reflux symptoms, a trial of treatment with an H<sub>2</sub> blocker or a proton pump inhibitor is justified.

### *Exercise*

Almost all young, active asthmatic subjects may provoke attacks by exercise, although their responsiveness to this form of challenge varies according to other factors such as associated allergen challenge and baseline bronchial reactivity and the ambient temperature. The typical exercise required to provoke an attack is several minutes of running, though a quick sprint for a bus on a cold winter morning may be sufficient. The bronchoconstriction usually starts at or towards the end of the exercise and lasts 20–30 min. The mechanisms have been discussed above.

### *Weather*

Almost all asthmatic patients notice effects of the weather on their symptoms and learn which individual patterns suite them best or least. Aside from the effects of air pollution and seasonal airborne pollen and spores, extremes of temperature seem most likely to provoke attacks in the susceptible. Notable epidemics of asthma have been described on many occasions in association with thunderstorms [380–382], although the causes of these are not understood and not all such storms are associated with epidemics. It has been suggested that in some cases they may be due to release by the associated rainfall of large

numbers of fungal spores or allergenic grass pollen particles, and epidemics are most likely to occur if the storm follows a period of high pollen counts [272,383].

### *Occupational factors*

Work-related factors are important provokers of asthma, and asthma is now the most common type of work-related respiratory disease in industrialized countries [384,385]. Occupational asthma can be defined as variable airways narrowing causally related to exposure in the working environment to airborne dusts, gases, vapours or fumes [386]. Most authorities now recognize that typical asthma may occur following exposure to high concentrations of irritant gases or fumes [387], the so-called reactive airways dysfunction syndrome discussed further in Chapter 36. This section concerns itself with asthma following exposure to a sensitizer. Symptoms usually commence within 2 years of starting the job, although this period is sometimes much longer, and may be associated with a particular place or process. Typically, the symptoms initially occur towards the end of the working day and in the evening, and are relieved at weekends and on holiday. As the condition progresses, so the symptoms become more persistent and may last over weekends and even for several weeks after work has ceased [385,388]. Indeed, there is no doubt that exposure to allergens, particularly those of low molecular weight, in the workplace can act as a trigger of persistent asthma that continues despite complete cessation of exposure; unless the patient ceases exposure relatively quickly after symptoms commence, this is the usual outcome [387,389,390]. Thus, if the patient presents for diagnosis when the condition has become well established, typical patterns of work-related peak flow rate changes may be absent. There are a number of factors that influence prognosis. Further occupational exposure in sensitized subjects leads to persistence and sometimes progressive deterioration of asthma, irrespective of any reduction of exposure to the specific sensitizer. Other determinants of an unfavourable prognosis are long duration of exposure before the development of asthma, long duration of symptoms before diagnosis, poor baseline pulmonary function, dual responses after specific challenge tests and the persistence of markers of airway inflammation in BAL and bronchial biopsies [388]. The diagnosis of occupational asthma is discussed in a later section.

Occupational asthma is considered for medicolegal purposes to be asthma provoked by some agent in the work process that was not present before the individual was so exposed. The agent (identified or not) should be specific to the workplace as well as causally related to the disease [386,389,391]. A previous history of asthma does not exclude a diagnosis of occupational asthma, but in such individuals the diagnosis is much more difficult to estab-

lish. People with pre-existing asthma are of course liable to develop exacerbations if they choose jobs in which allergen exposure is a problem. Atopic individuals are also at greater risk of developing asthma in jobs where they are exposed to one of the classical high molecular weight allergens, such as animal dander, grain dust or other organic debris. In general, however, this is not true of exposures to low molecular weight chemicals, where atopics appear to be at relatively little greater risk [392], with some exceptions such as platinum complex salts. Nor are non-atopics immune from asthma even when exposed to classical allergens, so prevention of the condition by screening out atopics is not usually a very effective means of control. More than one immunological mechanism must be involved in occupational asthma. The mechanisms of asthma due to small molecular weight substances are not known, and it is unlikely that classical IgE-mediated allergic processes are responsible in all cases. There is evidence to confirm that T-lymphocyte activation and local accumulation of activated eosinophils in the bronchial wall occurs in asthma of diverse aetiology [392]. It should be noted in passing that bronchoconstriction in response to workplace exposures may not always imply the potential of persisting hypersensitivity. For example, it may be a transient phenomenon provoked by irritant exposures, such as to smoke, chlorine, SO<sub>2</sub> or citric acid, or by exposure to the anticholinesterase organophosphate insecticides [393].

### *Causes of occupational asthma*

The list of proven causes of asthma in the workplace is long and inevitably increasing. For a detailed review, the reader is referred to the article by Chan-Yeung and Malo [394]. However, it is more important always to bear in mind the possibility of occupational factors, which may not have been recognized previously, and to make appropriate investigations than to remember a long list of known causes. The list may be simplified by subdivision into categories that may prompt a question in the history, i.e. exposure to animals or animal products, plants or their derivatives, and enzymes, drugs and chemicals. The best known of these are listed in Tables 34.1–34.3.

**Table 34.1** Causes of occupational asthma of animal origin.

Agent	Occupation
Cats, dogs, horses	Veterinarians
Rats, mice, guinea-pigs	Laboratory workers
Grain mites	Farmers
Locusts	Research workers
Moths, silkworms, flies	Breeding
Pigeons, chickens	Breeding, farming
Oyster, prawn, crab, salmon	Food production

**Table 34.2** Causes of occupational asthma of vegetable and bacteriological origin.

Agent	Occupation
Grains and flour	Farmers, millers, bakers
Hardwood dusts	Millers, joiners, carpenters
Castor, coffee beans	Processing
Gum acacia	Pharmaceuticals
Tragacanth	Sweet manufacture
Colophony	Soldering
Enzymes	
Alcalase	Detergent production
Trypsin	
Papain	Pharmaceuticals, food technology
Amylase	
Ispaghula	Laxative manufacture

**Table 34.3** Causes of occupational asthma of chemical origin.

Agent	Occupation
Isocyanates	Paints, varnishes, plastics
Epoxy resin hardeners	Adhesives, varnishes
Ethanolamines	Aluminium soldering
Formaldehyde, glutaraldehyde	Hospital workers
Azodicarbonamide	Plastics
Platinum	Refining
Nickel	Plating
Chromium	Leather tanning
Cobalt	Hard-metal work
Vanadium	Boiler cleaning
Persulphates, henna	Hair colouring
Reactive dyes	Manufacture, dyeing
Pharmaceuticals	Pharmaceutical industry
Penicillins	
Tetracyclines	
Cephalosporins	
Piperazine	
Psyllium	
Chloramine T	
Ceftazidime	

Important animal causes include small laboratory mammals, where urinary protein is usually the principal allergen [395–397], insects such as locusts [297], fruit flies [398] and honey-bee dust [399], grain mites [400], fowl mites [401], moths (including silkworms) and flies [299,402], birds such as pigeons and chickens [401,403], and molluscs such as oyster, prawn and crab [404,405]. Sensitization occurs as a result of exposure to airborne particles such as urine droplets, mite faeces or small fragments of insect parts. Prawn workers may be exposed because of the water jets used to blow the meat from the exoskeleton. Farmers and veterinarians may become sensitized to any number of animals that they handle, as may laboratory workers.

The best-known vegetable causes are wood dusts, espe-

cially from hardwoods such as western red cedar [389] and grain dusts [406–408]. The largest numbers of subjects sensitized to wood have been reported from sawmills, although joiners and carpenters not infrequently develop symptoms [409]. They can usually prevent attacks by avoiding the particular wood. It is probable that the active agent in hardwood dust is a small molecular weight chemical, plicatic acid, which can combine with serum albumin to form a sensitizing hapten [410]. In common with other types of asthma provoked by small molecules, atopic individuals do not seem to be at increased risk of western red cedar sensitization. Less is known of the immunological mechanisms of asthma caused by other wood dusts, although in view of their common characteristic of hardness it is likely that they act similarly. Grain dust contains a complex mixture of allergens and has been known to cause respiratory problems among bakers and millers since the eighteenth century. Flour itself may be allergenic, and not uncommonly sensitization to enzymes used in the process, notably  $\alpha$ -amylase, occurs [411,412]. Occasionally the grain may be contaminated by fungi and mites. The grain mites *Tyrophagus* and *Acarus* spp. have been shown to be an important cause of asthma in farmers in Scotland handling stored grain [413]. Other vegetable causes of asthma include castor and coffee beans [414,415], in workers manufacturing their products, and gums from acacia and tragacanth used previously in printing and currently in pharmaceuticals and sweet manufacture [416,417].

Colophony (or rosin), the residue that remains when oil of turpentine has been distilled from pine resin, is known to be an important cause of asthma [418,419]. It is used as a component of multicore solders and has widespread industrial application in the manufacture of circuitry in electronics. The principal component of the fume liberated when it is heated is a small molecular weight chemical, abietic acid. The mechanism whereby this provokes asthma is not known, although there is no evidence that it causes IgE-mediated sensitization. Asthma caused by colophony is commonplace in the electronic industry and again affects atopics and non-atopics, even though atopy may be a weak predisposing factor [420,421]. Occupational asthma caused by enzymes was first described in workers making so-called biological washing powders, where proteolytic enzymes derived from *Bacillus subtilis* were introduced into the product [422–424]. This problem has now been controlled by careful attention to industrial hygiene in the process [425]. Sporadic cases may be seen of workers sensitized to other enzymes such as trypsin, papain and amylase in plastic, pharmaceutical laboratory and food technology work [426–428]. Asthma caused by drugs administered to patients is discussed in Chapter 55. Pharmaceutical products or chemical compounds involved in their synthesis may also sensitize workers. Among these are penicillins, tetracyclines, cephalo-

sporins, piperazine, chloramine disinfectants and psyllium [429–435].

In recent years, the substances that have attracted most attention as causes of occupational asthma have been low molecular weight chemicals. Isocyanates, especially TDI but also the diphenyl methane, hexamethylene and naphthylamine compounds and prepolymers [436–444], are particularly important because of the large numbers of workers exposed in the production of polyurethanes and synthetic rubbers and in the use of foundry binding materials, varnishes and other surface coatings. Isocyanates are irritant substances and in high concentration can cause non-specific bronchial reactivity, although sensitized subjects react to extremely low concentrations. They are reactive chemicals but the method by which they cause sensitization is not known; there is no strong evidence that they cause their effect via hapten formation and an IgE-mediated reaction, though occasional subjects show a positive RAST to TDI-albumin complexes [445]. Isocyanates may occasionally also cause hypersensitivity pneumonitis (see Chapter 37).

Epoxy resins are polymers that are converted into solids by the addition of acid anhydrides or other chemicals as curing agents. Mixing of the two components in their use as adhesives, surface coatings or plastics may cause liberation of anhydride fumes that can produce asthmatic sensitization, as can heating materials containing them, as in meat-wrappers' asthma [446–448]. There are several such chemicals in use: phthalic, trimellitic, hexahydrophthalic, maleic and tetrachlorophthalic anhydrides. Trimellitic anhydride may also cause alveolitis, an influenza-like syndrome and haemolytic anaemia and haemoptysis [447,449]. These reactive chemicals do act as haptens, and both IgE and IgG antibodies have been described in exposed subjects [450,451]. Aliphatic amines are also potent causes of occupational asthma, described in shellac and lacquer handlers and also in aircraft fitters [452–454]. These compounds include ethylenediamine, dimethylethanolamine, triethylenetetramine and aminoethylethanolamine.

Several metals or their salts may cause bronchial (and skin) sensitization: complex salts of platinum in refining [455,456], nickel in polishing and plating [457], chromium in plating, printing and tanning leather [458,459], cobalt in coolants used in making and machining tungsten carbide (hard metal) and diamond polishing [460,461] and vanadium in cleaning residues from boilers which have burned oil containing the metal [462]. Exposure to cobalt in hard-metal work may also lead to an alveolitis and pulmonary fibrosis, so-called hard metal disease [463]. Asthma in aluminium refinery workers is probably due to fumes of fluoride rather than to the metal itself [464].

Many other chemicals have been described as occasional causes of asthma and no doubt many others will be in the future. Worthily of note are formaldehyde and

glutaraldehyde in hospital workers [465,466], azodicarbonamide (a blowing agent in plastic manufacture) [467], paraphenylenediamine in fur dyeing [468], various dyes in hairdressing [469] and aminoethylethanolamine in aluminium soldering [470]. Reactive dyes in the textile industry, when handled in powder form, are another cause that has on occasion proved fatal [471]. More recently, a large variety of causes have been reported including latex especially in rubber gloves used in hospitals [472], fungicides [473,474], and polyethylene shrink wrapping [475]. Latex allergy is becoming an important and increasing problem in hospitals, causing both allergic dermatitis and asthma. It is caused by liberation of particles of protein from the gloves, which are now generally made of cheaper, less well-washed latex.

Some studies have shown that asthma related to chemical and vegetable agents occurs more commonly in cigarette smokers. It has been speculated that this may be due to the effect of smoke on bronchial epithelium, improving access of the sensitizer to submucosal lymphocytes and mast cells [476,477].

Several mechanisms, including immunological, pharmacological and genetic, have been suggested as causes of occupational asthma, acting in concert with airway and neurogenic inflammation [392]. It is likely that more than one mechanism is operative, and it is certain that many more causes or 'inducers' of this problem will be identified in the future. The medicolegal and compensation aspects of occupational asthma have been well reviewed [478].

### Clinical course

The only certain things about the course of asthma are its variability and its unpredictability. However, some general points about the natural history can be made and are useful in discussing prognosis with patients and their relatives at the time of diagnosis. The course of asthma is usually one of periods of normality punctuated by attacks of cough, wheeze and breathlessness. Factors provoking attacks have been discussed above; however, attacks often occur without obvious provocation. They may be brief, as after exertion, or last several weeks, as after a viral illness. Between attacks, patients are usually free of symptoms though symptoms may be provoked by exercise or exposure to allergens. During symptomatic periods, patients are usually more sensitive to such stimuli than when well. In atopic asthmatics, exacerbations provoked by allergens are commonly accompanied by rhinitis, while perennial rhinitis of non-allergic but uncertain aetiology commonly accompanies non-atopic asthma. During periods of poor symptom control the characteristic features are variation of symptoms and expiratory flow rates within the 24-h cycle, usually being worst in the small hours and first thing in the morning and least troublesome in the early

afternoon [479,480]. Appropriate changes in the timing of this cycle occur in shift workers [481]. There has been much discussion of the cause of diurnal variation and, particularly, nocturnal deterioration in asthma. Suggestions that it might be related to feather pillows or mites in the bed do not explain its occurrence as frequently in non-atopic as in atopic patients. Circadian corticosteroid variation does not explain its occurrence in those on regular medication with these drugs. On balance, it seems likely to be related to increased vagal tone and reduced NANC tone acting on a hyperreactive airway at night [482,483]. It has been shown that bronchial inflammation is increased at night [484] and this is likely to contribute to airway narrowing and hyperreactivity [485].

When asthma starts in childhood, there is a reasonable probability that it will remit (sometimes temporarily) at about the time of adolescence and it usually improves at that age [486–488]. In a Finnish study, 108 asthmatic children were followed up to 20–24 years of age [489]; one-quarter were symptom-free, while another quarter had symptoms at least once a week, half had increased airway responsiveness but only 18% had a below-normal FEV<sub>1</sub>. Risk factors for persistence of asthma appear to be severe childhood asthma starting at an early age associated with atopic eczema. Asthma starting in adult life remits less frequently, except when it occurs simply as a prolonged response to a viral infection. The disease may start at any age, from infancy to extreme old age [37], and may announce itself with an acute severe attack, with increasing wheeze and breathlessness, or with persistent cough. When it presents in middle age or later in this insidious manner, especially if cough is a prominent symptom, it is very liable to be misdiagnosed as chronic bronchitis by the unwary physician. A patient developing asthma for the first time in adult life frequently gives a family history of the disease and atopy is a major risk factor [356], although personal allergic factors are much less important than in childhood, unless the asthma is occupational in origin. It is common clinical experience that older more severe asthmatic patients frequently develop a substantial degree of fixed airway obstruction, and the rate of decline in lung function tends to be accelerated in these patients [490,491].

Acute severe attacks, previously called status asthmaticus, occur spasmodically and unpredictably. They are usually provoked by one of the factors mentioned above. Some patients suffer such episodes frequently but some never (this condition is discussed in the next section). A relatively small proportion of patients develop progressive chronic disease that becomes largely irreversible, even to large doses of corticosteroids. This syndrome, chronic severe asthma, is also discussed below.

### Acute severe asthma

Acute severe attacks represent progression of airways nar-

rowing to the point where the patient is distressed at rest and may have signs of cardiac stress. Episodes may be of extremely sudden onset, as in an anaphylactic reaction, but more commonly build up over several hours or days. Often they are initiated by a viral infection and preceded by a period of a few hours or days during which asthmatic symptoms are increasingly troublesome, especially at night.

The symptoms are of increasing breathlessness, wheeze, cough and chest tightness, culminating in difficulty in talking or inability to do anything other than concentrating on breathing, usually in an upright position but sometimes crouching on hands and knees. Anxiety to the stage of panic is a usual and understandable feature. The patient sits up in bed or chair [492], wheezing is audible without the stethoscope, unless the patient is desperately sick, and the chest is visibly overinflated. Sweating may be profuse in severe attacks, and more often than not patients are pale and sweaty. If cyanosis is present this indicates life-threatening severe acute asthma. Considerable effort is clearly being expended on inspiration, the hyperinflated thoracic cage working at a great mechanical disadvantage, even though all accessory respiratory muscles are being used in an attempt to improve breathing. Cough is usually not prominent, as it is almost impossible for the ill patient to generate sufficient expiratory flow; if it is a feature, it is rarely productive of sputum. Indeed, production of sputum can be taken as an encouraging sign of recovery or indicative of an episode that at this time is not life-threatening. Tachycardia is always present, unless the episode has caused profound hypoxaemia. A paradoxical pulse (pulsus paradoxicus) is frequently detected; the extent of the fall in systolic pressure on inspiration may be as much as 50–60 mmHg and if present is a good indicator of the severity of the condition [493–495]. However it is not always present in patients with severe acute asthma and therefore its absence may be misleading [496]. Because of this, it has been withdrawn from the most recent British Thoracic Society guidelines on the management of asthma [497].

Assessment of the severity of the attack prior to treatment includes judging the degree of breathlessness by the patient's ability to talk (e.g. complete sentences in one breath) and measurement of heart rate and pulsus paradoxicus, peak flow rate and arterial blood gases [493,498]. Of these, the ability to talk, pulse rate and arterial blood gases provide the best indicators of severity and prognosis. The degree of breathlessness can be categorized conveniently according to the scheme of Sherwood Jones, which ranges from 'able to carry out housework or job with moderate difficulty (Grade 1A)' to 'immobilized and exhausted (Grade 4)' [498]. Blood gases, as discussed later, show hypoxaemia and hypocapnia initially, hypercapnia only occurring in the preterminal stages of an attack [499].

Even before the introduction of corticosteroids, the majority of attacks resolved spontaneously after several very frightening and stressful days. Nowadays, the use of aerosol and intravenous bronchodilators usually brings some symptomatic relief within minutes, while resolution of the attack can be expected to start some 6–12 h after the commencement of high-dose corticosteroids. A few patients prove resistant to this treatment and require several days or even weeks of steroids before the attack resolves, while some patients have attacks of such suddenness (or present for treatment at such a late stage) that assisted ventilation is necessary immediately. These matters are discussed in Chapter 35. A proportion of patients die of cardiorespiratory arrest in the course of such attacks, and management of asthma patients should foresee and plan to prevent this possibility.

### Chronic severe asthma

Some patients with long-standing asthma develop increasingly severe airflow obstruction progressively over several years. While this may occasionally occur in young people, it is more frequently seen in the middle-aged and elderly [500,501]. Sometimes it is due to bronchopulmonary aspergillosis but usually there is no clinically obvious cause. The characteristic feature is failure to respond, more than partially, to high doses of prednisolone [502], although sometimes change to an alternative corticosteroid in high dose (e.g. intravenous methylprednisolone or intramuscular triamcinolone acetate) may produce some improvement [503]. Bronchodilator responsiveness in these patients is usually preserved. The frequency with which this condition develops in asthma patients is not high but, because of the therapeutic problems it presents, it is disproportionately represented in specialist respiratory medicine clinics.

The pathology of the disease does not apparently differ from that of more steroid-responsive asthma [62]. Occasional such patients show unexpectedly dramatic improvement, sometimes lasting months, following a severe febrile illness; this was recognized by the generations of physicians before the advent of steroids, who occasionally treated such patients with fever therapy induced by injections of milk or vaccines. Understanding this syndrome, which is probably due to corticosteroid resistance [504–506], is an urgent priority of asthma research in order that appropriate therapy may be found. For the present, chronic severe asthma causes untold misery to large numbers of older asthmatics, misery compounded usually by the side-effects of high-dose corticosteroids. Glucocorticosteroid responsiveness in asthma can be defined as an increase in FEV<sub>1</sub> or mean peak expiratory flow (PEF), of 30% or greater during a 14-day course of prednisolone 40 mg daily, and glucocorticosteroid resistance as a less than 15% improvement in FEV<sub>1</sub> or mean

PEF, with the same 2-week treatment with prednisolone [507]. Glucocorticosteroid resistance is not caused by altered pharmacokinetics and the defect in asthmatics is not organ-specific [507,508]. Comparison of cells from normal individuals and from patients with corticosteroid-sensitive asthma has shown peripheral blood mononuclear cells and T lymphocytes to have different *in vitro* characteristics, especially with regard to their response to corticosteroids [504,505,509,510]. All aspects of corticosteroid-resistant asthma have been comprehensively reviewed [506].

### Bronchopulmonary aspergillosis

Skin sensitivity to *A. fumigatus* is commonly present in atopic individuals and occurs also in a proportion of otherwise 'non-atopic' patients with chronic asthma. The frequency with which this occurs varies between 16 and 38% in different studies which, being based on clinic populations, may be assumed to be biased towards the more severe end of the asthmatic spectrum [511–513]. In some of these patients, bronchial hypersensitivity to the fungus is also present, while in a small proportion attacks of asthma provoked by the organism are accompanied by a systemic illness with fever and malaise associated with radiographic evidence of peripheral patchy infiltrates or collapse of a lobe, segment or even a whole lung [514–516]. Sputum can be shown to contain hyphae of *A. fumigatus*, which therefore may be presumed to be growing in the airways. Characteristically, the sputum contains typical bronchial casts, with eosinophils, Curschmann's spirals, desquamated epithelial cells and hyphae (Fig. 34.20). The serum contains both IgE and IgG antibodies to *A. fumigatus*, and the total IgE is usually markedly raised. Both immediate and delayed skin sensitivity to intradermal injection of antigen are present [517–519]. Blood eosinophilia ( $1-3 \times 10^9/L$ ) is a common finding. The full-blown picture is known as allergic bronchopulmonary aspergillosis (one of the causes of pulmonary eosinophilia; see Chapter 38). Attacks are recurrent and tend to occur at first predominantly in the winter months. Untreated, an episode may last many weeks before resolving; recurrent attacks characteristically cause a proximal form of bronchiectasis, with evidence of distal pulmonary fibrotic changes [520,521]. Occasionally, especially in patients treated with long-term corticosteroids, typical radiographic exacerbations may occur without clinical symptoms [522–524]. Usually, however, attacks are noticed by the patient; they may present with chest pain and fever, as well as worsening of asthmatic symptoms, so appropriate therapeutic action can be taken. In patients with frequent attacks, progressive disease may occur leading to extensive, mainly upper zone, bronchiectasis and fibrosis. Radiological features are described in the following section. A diagnosis of allergic bronchopulmonary aspergillosis

**Fig. 34.20** Asthmatic sputum smear showing hyphae of *Aspergillus fumigatus* and a Charcot-Leyden crystal at bottom right (Papanicolaou  $\times 350$ ).

should be suspected in any patient with asthma who has an abnormal chest radiograph and a high peripheral blood eosinophil count. The diagnostic criteria include:

- 1 asthma (in most cases);
- 2 peripheral blood eosinophilia of greater than  $0.5 \times 10^9/L$ ;
- 3 presence or history of chest radiograph abnormalities;
- 4 positive skin-prick test to an extract of *A. fumigatus*;
- 5 serum precipitating antibodies to *A. fumigatus*;
- 6 raised total serum IgE;
- 7 fungal hyphae of *A. fumigatus* on microscopic examination of sputum.

Patients may sometimes present with typical attacks without having previously had asthma; in these cases diagnosis is often delayed [525,526]. Bronchoscopy is sometimes necessary to make a diagnosis and is of great value therapeutically. This often reveals thick tenacious plugs, which should be removed to restore an airway and to allow cytological examination to reveal the diagnosis. Occasionally, lobes or segments are excised surgically in the mistaken belief that bronchial occlusion has been caused by tumour. The histological features in the lung infiltrates are infiltration with eosinophils, areas of collapse, typical asthmatic bronchial inflammatory changes with intraluminal hyphae and sometimes intramural granulomas [527]. The more florid features of bronchocentric granulomatosis may sometimes be present [528].

The spectrum of response of the lungs to *A. fumigatus* is wide (see Chapter 21). Typical allergic bronchopulmonary aspergillosis may occasionally occur in people with aspergilloma and vice versa, and aspergillomas may occur as a sequel to treated invasive or allergic aspergillosis [529,530]. Very occasionally, allergic bronchopulmonary aspergillosis may develop features of invasive disease [531].

The immediate cause of the clinical manifestations of allergic bronchopulmonary aspergillosis appears to be the development of both immediate and delayed hypersensitivity to *A. fumigatus*, with an important cell-mediated component [532,533]. *A. fumigatus* spores are inhaled into the lungs since they are present in the air spora, predominantly in winter, the natural habitat of the organism being dead leaves, compost heaps and other decaying organic matter [534]. Since *A. fumigatus* is not by any means the most profuse fungal organism in the air, its special propensity to cause pulmonary problems requires explanation. This is probably related partly to its small spore size, which allows inhalation to alveolar level, and partly to its optimal temperature requirement of  $37^\circ\text{C}$ . In addition, its spores have developed sophisticated antiphagocytic defences that allow it to survive macrophage attack [535–537], and colonization may be facilitated by the pathological changes in the asthmatic's bronchial wall that expose the basement membrane [283]. A syndrome similar to allergic bronchopulmonary aspergillosis has been described occasionally in response to other fungal spores, both other species of *Aspergillus* and unrelated organisms such as *Curvularia* spp. and *Dreschlera* spp. It would be surprising if others were not to be described in the future, as the fungal air spora varies according to local climate and vegetation. For further discussion of these matters, see Chapter 21. The natural history of the condition is for recurrent episodes of pulmonary infiltration associated almost always with symptoms of exacerbation of asthma to occur over many years [538]. Between attacks, which tend to occur in autumn or winter when spores are most prevalent in the air, the patient is usually well. If attacks are treated promptly with oral corticosteroids, the condition does not usually result in progressive lung or airway damage, though early unrecognized or untreated

episodes often leave some localized bronchiectatic change [538]. The management of allergic bronchopulmonary aspergillosis is discussed in Chapter 35.

### Other complications of asthma

The most common complications of asthma relate to the long-term use of corticosteroid drugs. Facial changes, skin dystrophy, bruising, osteoporosis and vertebral collapse, and adrenal suppression are all commonplace and distressing features in chronic asthmatics. In children, growth retardation may be blamed on the drugs, but was a feature of chronic childhood asthma prior to their introduction [539]. In general the literature on the effects of inhaled corticosteroids on growth is reassuring, although long-term oral corticosteroid therapy, even in low doses equivalent to prednisolone 2.5–5 mg daily, significantly stunts short-term and intermediate-term growth and can reduce final height [540]. Treatment with inhaled budesonide in doses up to 400 µg daily seems not to affect growth adversely in children with asthma [541]. Higher doses can be seen to have an effect on short-term lower leg growth as assessed by knemometry; while no firm conclusions can be made about the long-term effects of inhaled corticosteroids, studies addressing this question suggest that children with asthma treated with these drugs usually attain a normal final height [542]. The question of the possibility of individually increased sensitivity to a growth-retarding effect of inhaled corticosteroids needs further study. Structural chest cage deformities caused by uncontrolled severe chronic asthma [543], such as pigeon chest and kyphosis, are now rarely seen in countries in which modern drug therapy can be afforded.

Other complications are relatively uncommon, except for respiratory infections. These are often difficult to differentiate from acute asthmatic exacerbations, especially as purulent sputum may be mimicked by sputum containing large numbers of eosinophils. Pulmonary infiltration on chest radiographs in adult asthmatics is very suggestive of allergic bronchopulmonary aspergillosis, although other eosinophilic pneumonias or segmental collapse due to plugging may be responsible. The latter is not uncommon in children [544]. Very rarely, lung collapse unrelated to aspergillosis may occur [545]. Cough fractures of ribs may occur, especially in osteoporotic bones, and acute attacks may rarely be complicated by pneumothorax or mediastinal and subcutaneous emphysema [546,547]. Even patients with long-standing chronic severe asthma occasionally develop pulmonary hypertension and cor pulmonale, and chronic hypercapnia is also a most unusual feature. When these complications do occur, the patient usually has cigarette-induced COPD as well; nevertheless, occasional non-smoking chronic asthmatics do ultimately develop cor pulmonale and, in contrast to the clinical findings, right ventricular hypertrophy at

necropsy is a not uncommon finding in chronic asthma [548].

### Physical findings and functional effects

The characteristic clinical findings in a patient with asthma are wheezes (sometimes, harking back to Laënnec, called rhonchi). They are usually polyphonic, indicating their origin from many airways of different calibre. A wheeze is generated by vibration in the wall of an airway on the point of closure, in the same way as a reed in a woodwind instrument generates a note [549]. The airway narrowing is due to smooth muscle constriction, mucosal oedema and mucous plugging. From this central principle of asthma derive all the physiological abnormalities, which may be considered in terms of primary alterations in pulmonary mechanics and secondary changes in gas exchange and cardiac function. However, the cardinal feature of asthma is its variability, and the main role of lung function testing is in demonstrating change in expiratory flow rates in response to bronchodilators or various forms of challenge. It should also be noted that lung function is often completely normal when the patient is in clinical remission, or even during the day at a time when nocturnal symptoms are troublesome. During the asthma attack there is widespread narrowing of airways and this has the effect of reducing airflow rates. Measurements of this by FEV<sub>1</sub>, PEF or flow rates at different lung volumes derived from the flow–volume curve therefore show reduction in proportion to the severity of the attack [550]. Inspiratory flow rates are also reduced, though not to the same extent as those on expiration. In partial compensation for the airway narrowing the patient breathes at a higher lung volume, which increases the (negative) pressure within the thorax acting to distend the airways. This, and the widespread closure and partial closure of small airways, results in increased residual volume and increased work of breathing. These changes are illustrated in Fig. 34.21, which shows a progressive increase in residual volume. As the attack becomes progressively more severe, tidal breathing moves up towards total lung capacity and the tidal expiratory flow rate approaches the maximal expiratory flow rate. At this point, the thoracic system is working on a part of the pressure–volume relationship that is relatively inefficient, large negative pressures being required to generate adequate tidal volumes. This inefficiency is due to the increased elastic recoil pressures in the lungs and thoracic cage, together with the shorter initial length of the intercostal and diaphragmatic muscles at high lung volumes. At the same time, the reduced vital capacity and the low flow rates available mean that adequate ventilation can be maintained only by increasing the frequency of breathing. Thus the patient in an acute attack expends a considerable amount of energy in maintaining rapid inspiratory efforts at high lung

**Fig. 34.21** Flow-volume curves in remission and during an asthma attack. Note that during the attack residual volume is increased and tidal breathing takes place at a high lung volume. Also during the attack, tidal expiratory flows approach maximal values.

volumes. Indeed, there is evidence that total lung capacity actually increases during an acute attack of asthma, thereby putting the patient's respiratory muscles at an even greater mechanical disadvantage [551–553]. These physiological features are easily seen in the patient with acute severe asthma, who sits upright fighting to breathe in, and are the reason for the increasing fatigue that occurs terminally in this condition.

At one time there was much discussion about the site of airway narrowing in asthma, as determined by physiological tests [554,555]. There is little purpose in such studies, and the validity of so-called tests of small airways resistance is dubious in subjects with the patchy changes one might anticipate in asthma. There is little doubt that airways at all levels, from the larynx to the bronchioles, may be narrowed in an attack; glottic and major bronchial narrowing have been seen at bronchoscopy and demonstrated physiologically [556,557], and widespread plugging of small airways seen pathologically is universal in fatal attacks, unless death has occurred within minutes of the onset of the attack. It would be expected that different patterns of obstruction would occur in different attacks. Irregular distribution of airway narrowing through the lungs has been demonstrated by studies using inert gas washout and by ventilation scanning using radioactive isotopes [558–560].

### Changes in gas exchange

The irregular distribution of ventilation of lung units men-

tioned above is matched by local reduction in perfusion, resulting in patchy but similarly distributed areas of reduced activity on ventilation-perfusion scans [560]. The mechanisms of this are likely to be reflex, due to local hypoxia, together with increased local alveolar pressure from the elastic recoil of overdistended parts of the lung acting on capillaries in alveolar walls. Thus a compensatory mechanism exists that permits excessive physiological shunting and thus hypoxaemia in the stable, less severe, asthmatic. The infrequency with which segmental or subsegmental collapse occurs despite widespread hypoventilation is suspected to be due to collateral ventilation between acini, maintaining an air supply to alveoli distal to blocked bronchi. The asthmatic in remission and in the early stages of an attack may therefore have evidence of gross unevenness of ventilation, with only slight increase in alveolar-arterial oxygen gradient and mild hypoxaemia. Similarly, the diffusing capacity for carbon monoxide is rarely reduced in asthma (a useful point in differentiating the chronic asthmatic from the patient with emphysema) and indeed during remissions is often raised [561,562]. The reason for this high  $DL_{CO}$  is not clear; it is not wholly due to a raised alveolar volume and may be related to increased pulmonary capillary blood volume, perhaps as a consequence of distension of the capillary bed by the increased negative transpulmonary pressure [563]. Small reductions in  $DL_{CO}$  may be found in chronic bronchopulmonary aspergillosis [520,538], after administration of bronchodilator drugs (perhaps due to increased mismatch of ventilation and perfusion when both airways and vessels respond to the drug) [563] and when the steady-state rather than the single-breath method is used [564].

However, there is in general a direct relationship in asthma between  $FEV_1$  and  $P_{aO_2}$ . The lower the  $FEV_1$ , as a patient deteriorates, the lower the  $P_{aO_2}$ , and in acute severe asthma the patient is often markedly hypoxaemic [499,565] (Fig. 34.22). This presumably relates to the inability of reflex changes in perfusion to match exactly the increasingly severe and diffuse reductions in ventilation as the attack progresses. In contrast to the case in patients with smoking-induced chronic airways disease, the asthmatic patient is able to respond to this acute episode by hyperventilation. Because of the shape of the oxygen-haemoglobin dissociation curve, this has minimal effect on hypoxaemia, only allowing a rise roughly in proportion to the reduction in  $P_{CO_2}$  in the alveoli. In contrast, however, hyperventilation of those units of lung still accessible to inspired air allows removal of sufficient carbon dioxide to maintain normal pressures of this gas in the arterial blood; indeed, during most of a severe asthmatic attack the  $P_{aCO_2}$  is below normal, and a rise to normal levels together with increasing hypoxaemia is an ominous sign. The arterial pH usually simply reflects the ventilation and, except in prolonged attacks,

**Fig. 34.22** Effects of increasing airflow obstruction on (a)  $P_{aO_2}$  and (b)  $P_{aCO_2}$ . Progressive decline in  $P_{aO_2}$  is accompanied by a fall in  $P_{aCO_2}$  until severe airflow obstruction, when a rise to, or above, normal levels may occur. (From McFadden & Lyons [565].)

metabolic compensation for respiratory alkalosis is unusual [566].

### Cardiac function

Cardiac function is not normally altered in asthma except in an acute attack and, as mentioned above, right-sided heart disease of sufficient severity to present clinical problems is rare even in patients with chronic severe asthma. Indeed, when such a patient does have evidence of cor pulmonale, other diagnoses such as smoking-induced COPD or recurrent pulmonary embolism should be considered.

In the acute severe attack, tachycardia and pulsus paradoxus are evidence of cardiac stress, and the ECG may show P pulmonale and inverted anterior chest T waves [493]. Few studies of the pulmonary circulation in such circumstances have (understandably) been carried out,

although there is little doubt that pulmonary arterial pressure would normally be raised both in response to hypoxaemia and as a consequence of the high intra-alveolar pressures [567]. These pressures are due to the high recoil pressure of the lungs when breathing towards the top of the pressure-volume curve and are, of course, transmitted directly to the pulmonary capillary bed in the alveolar walls. In very severe attacks requiring assisted ventilation, it is noteworthy that the high ventilator pressures required to inflate these already overinflated lungs commonly provoke a marked decrease in venous return that can result in cardiac arrest [45]. In patients with respiratory acidosis and high inflation pressures, attempts to normalize blood gases quickly are abandoned and 'controlled hypoventilation' is employed, providing an adequate  $P_{aO_2}$  can be maintained [568].

Perhaps also related to cardiac stress is the occasional occurrence of myocardial infarction during an acute severe attack [569]. Such episodes are usually painless and rarely fatal, being identified from ECG changes. Plasma free fatty acids are raised, presumably reflecting greatly increased sympathetic activity [570]; this, together with impaired coronary circulation, may be the explanation of infarction. It is reasonable to suppose that the lack of pain in such episodes may be related to raised levels of endogenous opioids, the stress of the attack being not dissimilar to that occurring during severe prolonged exercise in which painless infarction and raised  $\beta$ -endorphin levels may occur [571].

### Variability in function

The greatest value of lung function testing in asthma is derived from measuring variability in flow rates. Fortunately this requires only the simplest of equipment, a peak flow meter or spirometer; the portability of the former makes it invaluable. Three types of testing are within the scope of every physician: measuring response to bronchodilators, examining the effect of exercise, and measuring variability over a period of days or weeks, with or without a course of steroids. A fourth type, assessing the effect of challenge testing, is usually carried out by specialists.

Many asthmatic patients when first presenting to their general practitioner do so during an attack. Measurement of  $FEV_1$  or PEF, followed by two puffs of a fast-acting inhaled bronchodilator, a wait of a few minutes and repeat measurement help to confirm the diagnosis in most cases and give an immediate indication of the patient's likely responsiveness to further treatment. It has the added bonus of encouraging patients to believe that they have found a physician who understands their condition. However, there are a few snags to this simple test. It should be borne in mind that responsiveness to bronchodilator varies according to the degree of airflow

obstruction at the time of administration, and little or none would be expected in someone with no obstruction or in someone with very severe obstruction. In the latter case, poor access of the bronchodilator to the airways may be a partial explanation, though intravenous bronchodilator may not be much better and it is therefore probable that in this situation airway oedema and plugging are making the major contribution to the obstruction [572,573].

Exercise testing can also be carried out with ease in clinic or surgery, and finds its application in confirming a suspected diagnosis in a (usually younger) patient who is not obstructed at the time of presentation. The simplest procedure is to measure PEF or  $FEV_1$  and then to ask the patient to jog at a steady pace for about 8 min. While laboratory treadmill or bicycle are perfectly satisfactory means of ensuring appropriate exercise is taken and are necessary for scientific study of the effect of different forms of exercise [574] and therapy, lack of a laboratory should not be a deterrent to the physician; a hospital corridor, the adjacent street or a nearby staircase are adequate substitutes [575]. The response to exercise, as discussed previously, varies from time to time depending on the pre-existing bronchial reactivity. A patient with typical asthma shows a period of bronchodilatation in the early stages of exercise but by the end of 8 min usually has started to bronchoconstrict. The expiratory flow rates usually continue to decline for a few minutes after exercise has ceased, then gradually recover to normal over an hour or less depending on the severity of the initial fall [576] (Fig. 34.23). The recovery can be speeded up by administration of a bronchodilator.

Another method of confirming the diagnosis of asthma is to record measurements of PEF several times daily over

**Fig. 34.23** Time of maximal fall in peak flow rate after exercise in 112 tests on asthmatic patients. (From Hartley [152].)

a period of days or weeks. This is also of inestimable value both in the investigation of suspected provocative factors, such as occupational or environmental sensitizers, and in investigating patients in whom the history of episodic breathlessness is equivocal. For the latter purpose, it is usually sufficient to ask the patient to record PEF morning, midday and at bedtime, together with recordings during any attacks (especially if any occur at night). In patients with normal flow rates when first seen, this allows assessment of the amount and severity of variability, while in those with a persistently reduced PEF it allows a baseline to be measured for comparison with similar readings during a period of treatment. In many patients with relatively severe airways obstruction, there is doubt about whether asthma or cigarette-induced disease is the dominant condition, and monitoring of PEF during a 2-week course of high-dose prednisolone usually resolves this matter. In investigating possible occupational factors, it is desirable to ask the patient to record PEF more frequently, up to every 2 h during work [577]. Unfortunately, such records are very time-consuming to analyse, and a compromise number of recordings (four or five times daily) is usually adequate. This should be combined with a diary kept by the patient, noting work activities, times away from work and symptoms. The use of lung function in challenge testing is discussed in the section on diagnosis. Again, simple and repeatable tests such as  $FEV_1$  and PEF are ideal for this purpose.

## Radiological features

In most patients with asthma, either in remission or during an attack, the chest radiograph looks normal. Slight overinflation, with depressed diaphragm, laterally spread ribs and enlarged retrosternal airspace, may be seen in some patients during an attack and in some with chronic severe asthma [578,579]. In contrast to emphysema, the diaphragm normally retains its upwardly convex curvature and the pulmonary vessels do not show the same degree of attenuation. The most usual abnormality seen on the asthmatic radiograph is thickening of bronchial walls, as tramline shadows and rings close to the hilum [580]. This is a non-specific finding that is seen also in chronic bronchitis.

The most important function of a chest radiograph in asthma is the exclusion of other abnormalities. In acute attacks pneumothorax may (rarely) occur and may be difficult to detect clinically. There may be evidence of mediastinal and subcutaneous emphysema, usually in the absence of pneumothorax. If consolidation is present, it is likely to be due to pneumonia but the possibility of allergic bronchopulmonary aspergillosis should always be considered.

Episodes of allergic bronchopulmonary aspergillosis are characterized by recurrent fleeting pulmonary

shadows [538], although lobar or segmental collapse, nodular or band shadows may occur (Figs 34.24 & 34.25). If untreated they resolve only slowly over several weeks, but with corticosteroid treatment they may be expected to clear within days. In some patients they recur at the same site; equally, recurrences occur apparently at random sites

in the lungs. Recurrent episodes may, but do not always, lead to chronic lung damage [538]. This shows radiologically as tubular (tramline), 'gloved-finger' and ring shadows, lobar or segmental fibrosis and lung shrinkage (Fig. 34.26) and the end-result in severe cases may resemble the appearances in cystic fibrosis. CT or

**Fig. 34.24** Radiograph of patient with acute episode of allergic aspergillosis showing segmental consolidation in left upper lobe. This resolved after a 2-week course of corticosteroid.

**Fig. 34.25** Acute allergic aspergillosis showing segmental consolidation in both upper lobes.

**Fig. 34.26** Chronic allergic aspergillosis showing shrunken upper lobes with linear and ring shadows.

**Fig. 34.27** CT of a patient who had had repeated attacks of allergic aspergillosis, the first of which had resulted in bronchiectasis in the right lower lobe.

bronchography shows bronchiectasis [538] (Fig. 34.27), commonly though not always confined to more proximal bronchi, giving a characteristic appearance of normal-looking bronchi distal to the ectatic lesions.

## Diagnosis and investigation

In most cases the diagnosis of asthma is made readily from the history. An account of episodic wheezy breathlessness, interspersed with periods of normality, is sufficient evidence on which to suspect asthma. In children and younger adults almost nothing else can cause such symptoms. However, a few conditions do need to be considered in the differential diagnosis at different ages, as all can mimic asthma when the disease presents in a less typical manner. Further evidence in support of asthma comes from a history of marked diurnal variability, attacks in the small hours of the night, and provocation by strong smells, exercise, changes in ambient temperature and allergens.

In infants, acute respiratory infections and asthma are hard to differentiate, and this problem persists in early childhood. When it presents with predominantly respiratory symptoms, cystic fibrosis may also be misdiagnosed as asthma. In older children and adults, bronchiectasis may be associated with wheezy breathlessness and airflow obstruction mimicking asthma, although these patients usually have productive cough as their predominant problem. In adults there can be great difficulty in dif-

ferentiating asthma from COPD due to smoking. The two conditions coexist in many patients, and it is often impossible to be sure whether an asthmatic component is present without a formal trial of treatment.

Two other conditions must be considered in older patients presenting with wheeze, namely carcinoma of the larynx and proximal bronchial or tracheal tumours not visible on the chest radiograph. Both present with persistent symptoms rather than with attacks of breathlessness, although in this age group asthma also frequently presents in a similar manner. Both may cause wheezy breathlessness on exertion and at night. Clues may come from other symptoms, such as voice changes, haemoptysis or weight loss, but the diagnosis of main airway partial obstruction should follow the physical examination, when a fixed monophonic inspiratory wheeze or stridor is heard. Confirmation is obtained by laryngoscopy or bronchoscopy. Extrathoracic airflow obstruction causes disproportionate inspiratory obstruction (hence stridor) and this may be demonstrated in the laboratory on flow-volume loops. However, this investigation is usually less readily available and less specific than laryngoscopy/bronchoscopy.

Confirmation of the diagnosis of asthma is usually achieved by serial PEF monitoring, which in the majority of cases shows a diurnal variation of more than 15%, and the response to therapy. In most cases no other investigations are necessary. General support for the diagnosis is usually obtained by showing a response in ventilatory function (FEV<sub>1</sub> or PEF) to an aerosol bronchodilator or, in younger subjects, the demonstration of a fall in FEV<sub>1</sub> or PEF following exercise. A raised eosinophil count (above 5% of the total white cell count) is common in untreated asthma [581]. Sputum eosinophilia is a useful indication of an asthmatic type of airways reaction, though it does not invariably predict a response to corticosteroids [582,583]. The demonstration of all the histopathological features of the asthmatic exudate by examining stained sections of sputum fixed in alcohol or formalin is probably a more reliable indication of asthma than a sputum eosinophil count [5]. This technique is also useful for the demonstration of hyphae of *A. fumigatus*.

Skin-prick tests may be useful in identifying suspected provocative allergens. The tests should be chosen from the history and should include a control solution, the most common allergens (house dust, *D. pteronyssinus* and grass pollen or whatever airborne allergens are most common in the locality), together with any allergens that are suspected of causing the patient's reaction in the home or work environment. There is no point in routinely performing a large battery of skin tests. In general, RAST for specific IgE levels correlates closely with the results of skin-prick testing [584]; as it is more expensive and cannot be performed in the clinic immediately, most physicians manage without it in the investigation of most of their

patients. In the past, not all commercially available methods of allergy testing have been entirely reliable and care must be taken before using results of these tests in the decision about whether 'hyposensitizing' vaccines should be recommended [585]. The sensible physician relies on a good history and skin testing for the detection of suspected allergens, backed by selective use of RAST, reserving challenge testing for the few occasions when it is thought necessary.

The skin-prick test is performed by putting a drop of allergen on the skin, usually the front surface of the forearm, and lifting the skin lightly through the drop with the point of an intradermal needle. Blood should not be drawn. The test should be read about 15–20 min later. A wheal is a positive result and should be compared in size to that obtained with the control solution, as some subjects react simply to the prick. Intradermal injection of allergen can be used for showing delayed reactions. It requires a larger dose of antigen and there is a higher risk of provoking an anaphylactic reaction; this method of testing is best confined to specialized investigations of aspergillosis or allergic alveolitis and should not be used in outpatient clinics. It should be noted that a positive skin test does not prove that the subject has bronchial hypersensitivity to the allergen in question, but simply adds support to the clinical suspicion. Conversely, bronchial sensitivity may sometimes be present in the absence of skin sensitivity, and when this is suspected RAST may indeed be useful. RAST also has undoubted value in investigating food allergy and in following patients for a quantitative fall in titres after control of exposure, for example to occupational allergen or to pets.

### Challenge testing

When it is necessary to investigate provocative factors, challenge testing may be desirable. Normally the first step is to demonstrate a response to a particular environment in terms of changes in PEF over a period. As the suspect environment in most such cases is the workplace, it is often necessary to record PEF four to eight times daily during periods off work, periods at work and periods again off work. The differences may be immediately obvious on looking at the record or particular patterns may be noticed [586]. Figure 34.28 illustrates one such test, where flow rates were persistently lower (and a bronchodilator was required frequently) when the patient was at work. More complex patterns may show increasing fall in flow rates as the week progresses, carry-over into the following week and intermittent falls, depending on such factors as the frequency and duration of exposure and the length of time the patient has had asthma. Sometimes in individuals in whom the asthmatic response has been over a prolonged period, recovery of flow rates may take weeks after exposure ceases (Fig. 34.29). Occasionally in these

**Fig. 34.28** Peak flow record of a patient with allergy to rubber gloves worn in laboratory work. Upper trace was recorded while he was on holiday, lower trace while at work. During the latter period he had frequent need of his inhaler. The one fall when at home followed a drink of red wine, to which he was also allergic.

**Fig. 34.29** Peak flow record of female electronic soldering supervisor. Full recovery and reduction in diurnal variability did not occur until about 2 weeks after cessation of exposure to colophony.

circumstances, where the aetiological diagnosis remains uncertain and when it is important to find out, challenge testing may be necessary.

As far as possible, all inhalation challenge tests should include exposure to an 'identical' placebo. The patient should be admitted to hospital overnight and the substance administered in a manner mimicking as closely as possible exposure at work. For example, isocyanate exposure may be produced by mixing certain two-component varnishes and applying them to a surface. Flour or sawdust exposure can be produced by pouring the dust from one bowl to another. In one study, a patient who thought he reacted to powder from his surgical gloves was challenged with placebo powder (talc), glove powder (starch), gloves of a different but apparently identical latex and gloves with which he worked [587]. He only reacted to the last, which were subsequently shown to give off

traces of carene vapour, previously known as a potent skin sensitizer.

The effects of the challenge are most conveniently monitored by peak flow rate, which the patient can carry out at home for a few days before and on the morning of challenge in order to obtain a baseline. The measurements should be carried out every 5–10 min after challenge until the immediate reaction is over (if necessary, a bronchodilator aerosol may be given if a severe attack is induced) and then every 30 min until it is certain that a late reaction will not occur. Such late reactions, starting after 3–4 h and lasting about 24 h, are common after challenge and may require treatment with corticosteroids (see Fig. 34.9).

In some cases the only convenient way of administering the challenge is by nebulized aerosol of extracts of the suspect material. It is difficult to judge the dose, and it is

therefore wise to start with high dilutions given for only a few minutes. The advantage of an exposure which mimics that in the workplace is that the patient is unlikely to be given a dose higher than that received previously. Nevertheless, length of administration is a matter for judgement, based on assessment of the patient's history. Severe reactions can occur, and nebulized bronchodilators for the initial reaction together with corticosteroids and bronchodilators for the late reaction should be available. Challenge tests are, of course, affected by drugs. The initial response is blocked by bronchodilators and cromoglicate and the late response by corticosteroids. These drugs should therefore be stopped before challenge and this may lead to difficulties in control of the asthma and in interpretation of the results. In general, challenge tests should be carried out on patients whose asthma is in remission and who are managing without regular medication. The techniques and problems of aerosol challenge testing have been reviewed by Burge [588].

Two other types of challenge test may occasionally be necessary. If ingested drug-related asthma is suspected, a small dose of the drug should be given orally. The above-mentioned precautions of hospitalization, baseline inves-

tigations, placebo tests and cessation of antiasthma treatment should be taken. The dose should be estimated from the severity of previous responses but initially should not be more than one-tenth of that contained in the preparation under suspicion. The other type of challenge test is that related to investigation of food allergy. In the simple case, the suspected food can be administered in a suitably disguised form (e.g. in a capsule or down a nasogastric tube). In complex cases, it may be necessary to establish the patient on an allergen-free diet and gradually introduce other foods one by one until reactions occur [589]. A typical such exclusion diet might consist of lamb or mutton, gluten-free bread or rice, fresh fruit and vegetables (though reactions to these are not unknown), tea, coffee, sugar and water. If this diet results in disappearance of symptoms and recovery of lung function over 2 weeks, foods under suspicion may be added. Those most likely to cause reactions are ones containing artificial flavours and colours, nuts, milk, eggs and wheat. The investigation of food allergy is complex and the results of such tests are subject to some variability in most cases; therefore clinical importance should only be attached to clear-cut results from placebo-controlled challenges.

# ASTHMA: MANAGEMENT

GRAHAM CROMPTON

Asthma is a disease that affects people of all ages, in all parts of the world. Despite greatly increased knowledge of the immunopathological processes characteristic of the disease, and apparent improvements in treatment, morbidity (and in some countries mortality) is increasing rather than decreasing. It is extremely unlikely that a cure of asthma will be available for many years to come, but even without further pharmacological advance there is now great potential for improving the management of most asthmatic patients by encouraging more rational use of treatments already in existence. To encourage uniformity of asthma treatment, management plans and guidelines have been published in several countries. In general terms the contents of all the guidelines are similar, and it is hoped that a greater number of clinicians will become aware of these management recommendations in the future. A worldwide unified approach to the management of asthma would be the ideal. However, it is likely that the more wealthy nations will have to give the lead, since the resources necessary to educate patients and clinicians about management principles are considerable, and the financial burden of therapy would be too heavy for some of the less-developed nations.

The overall management of asthma has many similarities with that of diabetes, since in both diseases the aim is to allow the patient to be as independent as possible and to make treatment changes as appropriate to maintain clinical control. Professional advice should be readily available when self-management has not been successful, and for most patients there should be regular contact with a healthcare professional for review and advice.

## Aims and principles of management

The aims of management are to:

- recognize asthma;
- abolish symptoms;
- restore normal or best possible long-term airway function;
- reduce the risk of severe attacks;

- enable normal growth to occur in children;
- minimize absence from school or work.

The principles of management are:

- patient and family participation;
- avoidance of identified causes where possible;
- use of lowest effective doses of convenient medications minimizing short-term and long-term side-effects.

These aims and principles of management have been taken from British guidelines for the management of asthma [1] but are similar to statements in many other guidelines now in existence in many parts of the world. In general terms the major objectives are to allow all patients to lead symptom-free normal lives with the aid of treatments, free from side-effects, which can be adjusted and modified by informed patients themselves.

## Patient participation

Efficient management of asthma requires a partnership between the patient and family and the healthcare professional. At the outset it should be made clear that cure or spontaneous remission of chronic asthma in adults is unlikely and therefore treatment and supervision are likely to be required over a prolonged period. Education is essential to allow sharing of information about the nature of the disease and its treatment and to enable the patient and family to acquire understanding and management skills. An important stage of the education process is allowing and encouraging the patient and family to express fears and concerns about the disease and treatment, and to discuss both the clinician's and the patient's expectations of the condition and its management. Patients and parents require both verbal and written advice; ideally all asthmatics with more than mild disease should have a guided self-management plan.

## Self-management plans

All patients who have to make frequent decisions about the management of their asthma should be offered a

self-management plan, which in effect means most of those requiring treatment with an inhaled steroid in a dose of more than 800 µg daily. The common finding of controlled trials on patient education alone is that verbal, written, audio and video educational programmes can increase a patient's knowledge but without improvement in asthma morbidity [2–4]. Ideally the self-management plans should be written for, and tailored to, the needs of the individual patient, since these can be cost-effective in the short term if directed at those with moderate to severe disease [5]. However, this is rarely possible and standardized plans that can, in part, be tailored for each asthmatic are commonly used. The most popular plans are based on a three-colour system (green, amber and red) and carry advice about management actions depending upon symptoms and peak expiratory flow (PEF) values.

**1 Green.** Symptoms under control and PEF greater than 80% of predicted or best: continue to use steroid inhaler regularly in the same dose, and use bronchodilator inhaler as required.

**2 Amber.** Symptoms not well controlled or PEF less than 80% but greater than 50% of best or predicted: double dose of steroid inhaler and use bronchodilator inhaler as necessary or regularly every 4 h.

**3 Red.** Distressing symptoms not responding to the bronchodilator inhaler or PEF less than 50% of best or predicted: start oral steroid treatment immediately and obtain medical help.

Plans need to be tailored to individual patients and their local healthcare circumstances so that they know when to contact the general practitioner, call an ambulance by using the emergency telephone code, attend the nearest hospital emergency department or use a respiratory unit self-admission service [6–9]. Written personalized management plans are essential for patients with poorly controlled asthma; in these patients, if the three-colour system is used, it is probably appropriate to omit the amber zone to encourage early aggressive intervention in the event of deteriorating asthma. Written educational materials should be available to supplement self-management plans since these materials are likely to help patients accept their diagnosis and gain confidence in coping with its effects.

It is difficult to prove beyond doubt that self-management plans are effective in the long term. Controlled studies show evidence of benefit by their reduction of hospital admissions, courses of oral steroids and nebulized bronchodilators, although there are questions concerning 'enthusiast bias' compromising outcomes [10,11], i.e. patients who are perceived to be likely to benefit from plans tend to receive them and operate them [12,13]. This may be the explanation of the widespread clinical acceptance that self-management plans work despite the doubts raised by analysis of controlled trials [4,5]. It is likely that

the success of management strategies depends to a considerable extent upon the healthcare professional who issues the self-management plan. He or she should be known and trusted by the patient, be readily accessible by telephone and ideally should be the person who reviews the patient at follow-up. Appropriately trained practice nurses with the time, enthusiasm and accessibility to patients could be the ideal choice [13], although it is appreciated that in many areas these individuals may not exist. The major problem in asthma management is translating the theory of good asthma care into everyday practice. There are marked differences between patients' self-management knowledge and their actual behaviour in an acute attack [14]. Self-management plans appear to be the best available option at present [15,16], although these alone are unlikely to overcome the major problem of compliance known to exist in a large number of patients with asthma [17,18].

### Peak flow monitoring

The variable orifice PEF meter was introduced in 1959 [19]. Since then a number of lightweight PEF meters have become available, and are commonly used in both the diagnosis and management of asthma. In the last decade self-management plans using PEF monitoring have become widely used [11,13]. Peak flow monitoring is used for (i) diagnosis (see Chapter 34), (ii) monitoring the effect of treatment, particularly the effects of treatment changes, (iii) self-management plans, especially in patients with poor perception of symptom severity [20] and in the day-to-day management of the patient with brittle asthma, (iv) investigation of suspected occupational asthma (see Chapter 34) and (v) research.

### Avoidance of causes and non-specific triggers and aggravating factors

Specific causes of asthma are rarely known except for some occupational sensitizers and aeroallergens. Physical factors, such as exercise, strong smells, cold, sudden changes in ambient humidity and temperature, cigarette smoking and smoky atmospheres, can trigger episodes of asthma or make chronic symptoms more troublesome. All patients should, of course, be encouraged not to smoke and also to avoid passive smoking if possible. Unfortunately a surprising number of asthmatics continue to smoke even though they realize it aggravates their symptoms. It is difficult to modify climatic conditions; however, any suggestions about modifications to the home environment should include the advice that ideally there should be, as far as possible, an even temperature and humidity in all rooms. The control of exercise-induced asthma requires therapeutic intervention rather than avoidance of exercise.

### Allergy avoidance

The increase in prevalence and severity of asthma in westernized countries may be due partly to increase in exposure to indoor aeroallergens [21]. The logical approach to the treatment of asthma involves avoidance of allergens where possible, including occupational sensitizers, together with the early intervention of anti-inflammatory therapy, usually inhaled steroids. Evidence is now accumulating that aeroallergens, particularly the house-dust mite and animal danders, are major independent variables in the prediction of asthma in different populations [22,23]. Exposures during the neonatal period are thought to be critical in the development of atopic sensitization [24] and avoidance of perennial aeroallergens and/or food allergens during early life may delay or even prevent the onset of atopic sensitization and allergic manifestations [25,26]. An advance in the evaluation of allergen avoidance has been the identification and characterization of the major allergenic determinants of common perennial allergens, namely *Der pI* (dust mites), *Fel dI* (cats) and, more recently, *Can fI* (dogs). This has enabled the development of monoclonal antibodies that allow accurate measurement of major allergens in dust samples and airborne exposure [27–29]. Ideally the efficacy of any allergy avoidance measure should be assessed by measurement of the reduction or elimination of allergen as well as by clinical response [30,31]. Barrier bedding methods, removal of carpets, regular cleaning and application of liquid nitrogen to bedding and furnishing have been associated with a reduction in house-dust mite levels [32–35]. The value of acaricides in reducing mite allergen levels remains controversial [32,36] and on the evidence currently available these products cannot be recommended for routine use. In children, barrier bedding methods combined with regular cleaning and removal of carpets appear to be effective in reducing bronchial hyperresponsiveness [36,37], but unless these arduous and often expensive prophylactic measures can be carried out fastidiously they usually have little clinical benefit. Animal allergens are difficult to avoid and eradicate as long as the pets remain in the home. After the departure of a cat from a home environment, several months of vigorous cleaning is necessary in order to reduce cat allergen load to clinically acceptable levels [38]. Washing a cat every week for 4 weeks has been shown to reduce the airborne cat allergen levels when the washing was combined with vigorous cleaning measures and removal of bedroom carpets [39], although this cannot be regarded as a substitute for removal of the animal from the household environment. A major source of animal dander allergen is contaminated clothing. High levels of *Can fI* have been demonstrated on schoolroom desks and chairs but not on floors, suggesting contamination from children's clothing from pets at home [29].

It is impossible to avoid pollens. Simple advice includes

wearing spectacles or sunglasses, remaining indoors during periods of high pollen counts and keeping windows closed particularly in high buildings and cars. Walking in open grassy spaces should be avoided, especially during the evening and night when pollen counts tend to be at their highest. However, these lifestyle modifications are often unacceptable, particularly by those whose atopic symptoms are not severe and easily controlled by pharmacological agents.

Those asthmatics who give a history of symptoms on allergen exposure and who have a positive skin-prick test to the same allergen should be given advice about appropriate allergen avoidance measures, although advice about pets is rarely taken [30,31]. Such advice should not be given because of a positive skin-prick test in the absence of historical evidence of allergen hypersensitivity. Negative skin tests are helpful in excluding an allergic basis for asthma, providing they have been performed correctly at a time when the patient has not been taking an antihistamine. Serum allergen-specific IgE concentrations by radioallergosorbent test provide an alternative to skin tests, but in general are more expensive and perhaps less sensitive. Recognition of an occupational sensitizer is of extreme importance, since removal from exposure may result in improvement or remission of asthmatic symptoms; unfortunately this does not occur in every case. Food and food additives are a much less common, although important, cause of asthma. When genuine food allergy exists it is usually readily detected and the offending item of diet can be avoided. Many patients believe that certain foods have caused or made their asthma worse and modify their diets or those of their children. With these patients it is often difficult or impossible to confirm or exclude food allergy. Milk products and eggs are commonly incriminated and in some patients with severe disease a strict exclusion diet can be tried in an attempt to establish whether or not foods are causing asthma. Although the problem appears to be rare in adults, there can be no doubt that food allergens during early life play some role in the onset of atopic sensitization and allergic manifestations [25,26].

### Drug avoidance

All  $\beta$ -adrenoreceptor antagonists are absolutely contraindicated in all patients with asthma. Even eye-drops containing one of these drugs can precipitate severe acute asthma. Aspirin can also induce worsening of asthma, which can be severe and is sometimes, but by no means always, accompanied by urticaria. Aspirin-sensitive asthmatics are usually adults with a history of nasal symptoms often due to nasal polyps. Other non-steroidal anti-inflammatory drugs can make asthma worse and all should be used with great caution in asthmatic individuals.

### Patient compliance with treatment

Poor patient adherence to prescribed medications has been shown to be a widespread problem in asthma [40–42] and has been linked to increased morbidity [43] and mortality [44]. Poor compliance with treatment in general is difficult to identify by routine clinical assessment [45] and there does not appear to be any association between compliance and age, sex, socioeconomic group, personality traits or level of education [46]. Patients' attitudes to treatment are likely to influence how they cope with their illness and use their treatment [47]. Inappropriate over-emphasis of the side-effects of corticosteroids leading to rapid reduction of dose or withdrawal of treatment could be a factor contributing to the deaths of some patients from severe acute asthma [15,44,48]. There is no simple method of improving treatment compliance in asthma, nor is there any way of identifying patients likely to benefit from intervention programmes. All patients must therefore be assumed to be poor compliers and all should receive similar, but individually tailored, self-management plans and education about the disease and the treatments used to control it.

### Drug treatment

Avoidance of allergens and non-specific aggravating factors may result in the disappearance of symptoms in some patients but in the majority some form of drug treatment is also required. This may be intermittent in episodic or seasonal asthma, while in adults the disease is usually chronic and long-term treatment has to be planned. There are two principal aims in the treatment of all patients with chronic asthma: (i) the rapid achievement of symptom control and optimal or best lung function; and (ii) maintenance of symptom control and best lung function. Initially this usually requires the use of a steroid, either orally or by inhalation, to achieve rapid control of symptoms and best lung function. Once this has been achieved, a step-down of treatment is usually possible in all but those patients with very severe chronic disease. Long-term maintenance therapy in most patients has to be with an inhaled steroid since this is the most effective treatment available for the control of the asthmatic bronchial wall inflammation.

The drugs used in the treatment of asthma can be broadly split into two categories: the  $\beta_2$ -agonist bronchodilators, sometimes called 'relievers', and the antiasthma inflammatory agents, sometimes called 'preventers'. However, there are other bronchodilator drugs, such as the anticholinergics, which have a useful but less major role than the  $\beta_2$  agonists, and theophylline. Traditionally, this drug has been classed as a bronchodilator but has now been found to have some anti-inflammatory activity in addition, though its role in the

treatment of asthmatic inflammation has still to be established. The development of long-acting inhaled bronchodilators and the production of oral sustained-release preparations of shorter-acting drugs has made it more difficult to categorize drugs simply as relievers and preventers; nevertheless this naive classification is of value in the education of patients and in the production of management plans and educational literature.

## Management of chronic asthma

### Drugs used for the relief or suppression of symptoms (the relievers)

#### $\beta_2$ adrenoreceptor agonists

The  $\beta_2$  agonists are bronchodilators that give symptomatic relief but have no major beneficial effects on the underlying bronchial wall pathology. Indeed regular use of short-acting  $\beta_2$  agonists has been questioned because of the possibility that such treatment might have a detrimental effect on the control of asthma, possibly by increasing bronchial hyperresponsiveness either during treatment or soon after its withdrawal [49–53]. Since  $\beta_2$  agonists only give symptomatic relief, there seems little reason to encourage patients to take them regularly. If regular treatment is necessary for relief of symptoms this should stimulate the prescription of an anti-inflammatory preparation or an increase in its dose.

#### *Inhaled short-acting $\beta_2$ agonists*

The  $\beta_2$  agonists relax airway smooth muscle and enhance mucociliary clearance. They also decrease vascular permeability and may modulate mediator release from mast cells and basophils, but they do not have any clinically relevant beneficial effects on the underlying chronic inflammatory disorder of the asthmatic airways. Short-acting  $\beta_2$  agonist inhalers should be used as necessary to relieve symptoms. Regular treatment with these compounds should be avoided wherever possible, unless the results of clinical trials now in progress show that such treatment is not harmful in terms of increasing bronchial hyperresponsiveness or adversely affecting the overall control and prognosis of asthma [49–54]. The International Consensus Report on Diagnosis and Management of Asthma [55] suggests that if a patient has to use a short-acting bronchodilator more often than three times a week this indicates asthma of sufficient severity to warrant regular treatment with an anti-inflammatory or prophylactic drug. The British guidelines [1] suggest that this form of treatment would be appropriate if a bronchodilator inhaler has to be used more than once a day. It follows therefore that inhaled bronchodilator therapy alone should only be used by patients with mild asthma. However, all patients able to

use an inhaler should have one, to be used for symptom relief as necessary, irrespective of the other treatments required for their asthma. The inhalation of a short-acting bronchodilator prior to exercise is often necessary to prevent exercise-induced asthma.

All patients with asthma should be aware that a  $\beta_2$  agonist bronchodilator inhaler only provides short-term relief of symptoms, and that the development of asthmatic symptoms leading to more frequent use of this inhaler is a sure sign of worsening of asthma, which usually requires extra anti-inflammatory therapy. Little, short-lived or no response to a bronchodilator inhaler heralds the onset of potentially life-threatening asthma. All patients should be aware of this and should know that in this situation they should seek medical help at once.

The most commonly used  $\beta_2$  agonists are salbutamol, terbutaline and fenoterol. Fenoterol has recently lost some of its popularity because of the possibility that adverse effects may be more likely with this drug than other  $\beta_2$  selective bronchodilators [53,56–59]. For the relief of mild to moderate symptoms, the doses of salbutamol and terbutaline usually recommended are 100–200  $\mu\text{g}$  and 250–500  $\mu\text{g}$  respectively. Considerably larger doses are necessary for the treatment of severe acute asthma. The duration of action of these drugs is 4–6 h and the onset of activity is rapid, maximum bronchodilatation being achieved within 15 min after inhalation. Rimiterol is a  $\beta_2$  agonist with a shorter duration of action (1–2 h) because, unlike salbutamol and terbutaline, it is rapidly metabolized by the enzymes catechol-*O*-methyltransferase and monoamine oxidase. The recommended dose of this short-acting  $\beta_2$  agonist is 200–400  $\mu\text{g}$  as required for symptom relief.

### *Long-acting $\beta_2$ agonists*

Slow-release oral formulations of salbutamol and terbutaline are available and these increase the duration of activity of these bronchodilators considerably compared with conventional oral tablets. Prodrugs are also now available which, when given orally, also greatly increase the duration of bronchodilatation (e.g. bambuterol is a prodrug of terbutaline, to which it is metabolized by hydrolysis). In general, however, inhaled therapy is preferable to oral since the inhaled route allows more rapid onset of bronchodilator activity and with a minute fraction of the dose necessary to achieve a similar clinical response via the oral route; this therefore reduces the risks of adverse effects [60].

The production of  $\beta_2$  agonists with a long duration of action when administered by inhalation has created a new era of bronchodilator therapy [61]. Salmeterol has a molecule with a long lipophilic tail that adheres tightly to regions in the receptor or adjacent to it while its head engages the active site. Even when displaced by an antag-

onist its activity resumes after the antagonist is washed free [62]. Eformoterol is even more potent but less adherent, its high lipophilicity retaining it in the receptor region. These long-acting bronchodilators have the advantage of being effective when used twice daily, although their role in the routine management of the asthmatic patient is far from clear. They do not have any clinically relevant anti-inflammatory effects and therefore should not be used as primary treatment of asthma, since patients who require more than occasional use of a short-acting  $\beta_2$  agonist should be treated with an anti-inflammatory drug, usually an inhaled corticosteroid [1,55,63]. Salmeterol has been shown to be effective in the treatment of asthma of almost all degrees of severity [62–69], and its long duration of action is obvious convenient for patients. However, the controversy about the possible dangers of regular treatment with short-acting  $\beta_2$  agonists [49–59] must be considered before recommending the regular use of drugs like salmeterol and eformoterol. Indeed, it could be postulated that if short-acting  $\beta_2$  agonists are in any way detrimental when given regularly in the long-term management of asthma, there could be greater problems with long-acting  $\beta_2$  agonists because they are more potent bronchodilators [49,51,70]. The more effective and prolonged bronchodilator efficacy of drugs like salmeterol could allow more specific and non-specific bronchial insults with irritant or allergen triggers before bronchoconstriction breaks through and hence the resulting acute episode could be more severe than one prevented by short-acting bronchodilator therapy. This theoretical danger has not been a problem in clinical practice in postmarketing surveillance studies of salmeterol; nevertheless the drug's use should be restricted to patients whose asthmatic symptoms are not controlled by inhaled corticosteroid therapy in doses unlikely to be associated with long-term adverse effects. The major debate about long-acting inhaled bronchodilator treatment is whether to start salmeterol or eformoterol if asthma is not well controlled with low-dose or high-dose inhaled corticosteroid therapy [71]. It has been pointed out that the much-publicized asthma guidelines [1,55,63] vary somewhat with regard to recommendations about drug use as well as classification of asthma severity [72]. Salmeterol is recommended for patients who have local laryngeal or oropharyngeal adverse effects of inhaled corticosteroids that do not allow high-dose therapy to be used [1]. Also, it would appear to be sensible to use this form of treatment once daily at night for patients already on an inhaled corticosteroid but who continue to have more than occasional nocturnal symptoms [60]. The addition of salmeterol to the treatment of patients whose asthma was not well controlled by treatment with a low dose of inhaled beclomethasone (beclomethasone) dipropionate (200  $\mu\text{g}$  twice daily) has been shown to be at least as effective as increasing the dose of inhaled beclomethasone (500  $\mu\text{g}$  twice daily) [71]. Studies

are now in progress in which attempts are being made to assess the control, or the suppression, of markers of inflammation by low-dose inhaled corticosteroid therapy plus long-acting inhaled  $\beta_2$  agonists compared with high-dose inhaled corticosteroid therapy in the treatment of patients with asthma whose symptoms are not well controlled by inhaled corticosteroid treatment in conventional low doses. The preliminary results of these studies suggest that long-acting inhaled  $\beta_2$ -agonist bronchodilator preparations are not associated with adverse effects. The role of eformoterol is likely to be more controversial than that of salmeterol because it has a much more rapid onset of bronchodilator activity and could therefore be used as a relief inhaler with a long duration of activity.

#### *Side-effects of $\beta_2$ agonists*

Large doses of  $\beta_2$  agonists can produce adverse metabolic and cardiovascular effects [73–75]. However, these events only occur when very large doses are used and even then are rarely of clinical importance. The  $\beta_2$  agonists are extremely safe drugs even when large doses are used, especially when given by inhalation and with oxygen. Unwanted cardiovascular effects include tachycardia, increased cardiac output, inotropism and ECG changes. Cardiac dysrhythmias are usually asymptomatic and rarely occur in patients who do not have pre-existing heart disease. General systemic effects include hypokalaemia and hyperglycaemia, increased free fatty acids, hypomagnesaemia, increased blood lactate and uterine relaxation. The only general unwanted effect that often causes patient concern is skeletal muscle tremor which, while not serious, can be distressing [76]. The individual response to tremor is highly variable but to some extent is dose dependent and, unlike bronchodilatation, tachyphylaxis occurs rapidly in the majority of patients. Tremor therefore is usually only a problem when  $\beta_2$  agonists are being given for the first time.

The predictable physiological adverse effects of  $\beta_2$  agonists rarely cause any serious clinical events. Most depend on route of administration and dose. Conventional doses administered by an inhaler for 'as-necessary' relief of the symptoms of chronic asthma can be assumed to be free from all unwanted effects, except for tremor in a few patients. Larger doses given orally, by inhalation or intravenously are associated with demonstrable unwanted effects, but only rarely are these of clinical significance. High-dose treatment for the control of chronic persistent asthma should of course be avoided; however, large doses of  $\beta_2$  agonists, usually by inhalation, are essential for the treatment of severe acute asthma and patients should not be denied this treatment simply because of the theoretical risks of adverse effects.

#### **Theophylline**

In the USA in the 1970s and early 1980s, theophylline (1,3-dimethylxanthine) was the most commonly prescribed bronchodilator. Detailed study of its pharmacokinetics and the development of sustained-release preparations, often monitored by theophylline serum levels, improved the therapeutic value of this drug by increasing its efficacy and decreasing its adverse effects. However, emphasis on the importance of anti-inflammatory therapy coupled with the simplicity and assumed safety of inhaled  $\beta_2$  agonists led to a decline in its use. It still has a role in the management of nocturnal asthma resistant to other forms of treatment, and is prescribed for many patients with severe chronic asthma in an attempt to avoid oral corticosteroid therapy. Paediatricians use theophylline more often than clinicians treating adult patients with asthma, mainly because it is easier for children to be treated with oral preparations, because many are unable to use inhalers and perhaps also because young children are less likely to be aware of side-effects. Theophylline relaxes smooth muscle by inhibition of phosphodiesterase and probably via other mechanisms [77]. A serum theophylline concentration of 10–20  $\mu\text{g/mL}$  was recommended, since below this range bronchodilatation is unlikely and above it symptoms of toxicity are common [78,79]. A dose–response relationship can be shown in chronic stable asthma with increasing serum concentrations of theophylline up to 20  $\mu\text{g/mL}$ , serum concentrations of 15 and 20  $\mu\text{g/mL}$  achieving bronchodilatation similar to that of conventional doses of salbutamol administered by metered dose inhaler (MDI) [80]. In most patients there is also a direct relationship between serum theophylline levels and side-effects, the most troublesome being nausea, vomiting, headache, nervousness and irritability. Because these toxic effects are common, the popularity of theophylline has declined markedly. There is an additive bronchodilator effect when theophylline is given in combination with  $\beta_2$  agonists [81–83], and in an attempt to decrease adverse effects low doses of theophylline preparations have been used in combination with salbutamol or terbutaline. However, this therapeutic approach requires regular  $\beta_2$  agonist, which should be avoided in the treatment of asthma whenever possible. Theophylline has been shown to increase the contractility of the diaphragm and render it less susceptible to fatigue [84], and also to increase maximal transdiaphragmatic pressure [85]. However, these actions of the drug are not likely to be of much clinical significance in asthma, except perhaps in severe acute episodes. Of much more interest recently has been the discovery that theophylline has anti-inflammatory properties, although the relevance of these to the treatment of asthma is far from clear. Type IV phosphodiesterase inhibitors, including theophylline, have been shown to effect changes in the activity and function of macrophages

[86,87] and lymphocytes [88,89]. Theophylline has been shown to reduce eosinophil infiltration of the airway [90] and to produce a reduction in eosinophil activity after prolonged treatment [91]. Also, unlike  $\beta_2$  agonists, theophylline modulates the late asthmatic response [92–95]. It has been suggested that theophylline may provide clinical effects comparable to those of low-dose inhaled corticosteroids in selected asthmatics [96,97]. The evidence suggests that theophylline has anti-inflammatory properties at doses lower than those necessary to achieve the conventional therapeutic serum level (10–20  $\mu\text{g/mL}$ ) required for optimal bronchodilatation. However, the role of theophylline in the treatment of the basic underlying eosinophilic inflammation of asthma has yet to be determined, and may be minimal. In the future, low-dose theophylline in combination with other drugs may become more established in the management of mild to moderate chronic asthma, although until more knowledge of the efficacy of such treatment is available oral theophylline therapy should be reserved for patients whose asthma is not controlled with conventional doses of inhaled corticosteroids. However, intravenous aminophylline continues to have an important role in the management of patients with severe acute asthma.

#### Anticholinergic agents

The drugs of this category (muscarinic antagonists) most widely used in the treatment of reversible airways disease are ipratropium bromide and oxitropium bromide. It is generally accepted that they are more effective in chronic obstructive pulmonary disease, i.e. chronic bronchitis and emphysema, than in chronic asthma [61]. In chronic stable asthma, ipratropium bromide produces a smaller response of delayed onset compared with salbutamol [98], although older asthmatics may respond better to anticholinergic agents than do younger patients [99,100]. In chronic asthma these drugs are usually reserved for use in patients who have not responded to conventional doses of an inhaled corticosteroid, when they are added to the treatment regimen as regular inhaled therapy (ipratropium bromide 20–40  $\mu\text{g}$  three or four times daily, or oxitropium bromide 200  $\mu\text{g}$  two or three times daily). Ipratropium bromide is of much greater value in the treatment of the severe acute episode than it is in the routine treatment of most patients with chronic asthma.

#### Drugs with anti-inflammatory properties used to influence the underlying inflammatory mechanisms of asthma (the preventers)

##### Sodium cromoglycate (cromoglycate) and nedocromil sodium

Sodium cromoglycate was first synthesized and its use in

asthma reported in a small trial in 1967 [101]. Its clinical efficacy was established in both adults and children in a series of clinical trials performed in different parts of the world [102–111], although in recent years its use has been almost completely restricted to the treatment of childhood asthma [112–114]. In the main this has been due to the often irrational fears of treating children with inhaled corticosteroids, sodium cromoglycate being preferred because it is virtually free from side-effects. This drug continues to be prescribed as first-choice treatment for atopic asthmatic children, particularly those with exercise-induced asthma, despite reports of early treatment failure and greater efficacy of low-dose inhaled corticosteroids [115–119]. To be optimally effective it has to be taken regularly at least four times daily and this very frequently leads to problems with compliance, which may be the explanation of treatment failure in some patients. Sodium cromoglycate has no role in the treatment of severe acute asthma.

Nedocromil has an extremely good safety record, although some patients find its taste unpleasant. An attempt to disguise this has been made by adding mint flavouring to the inhaler. The role of this drug in the management of chronic asthma is difficult to define [120–123]. It has little place in primary treatment, since its anti-inflammatory properties and clinical efficacy are inferior to those of inhaled corticosteroids. However, it may be of value in patients not well controlled by conventional doses of an inhaled corticosteroid and should be used as a corticosteroid-sparing agent in patients on oral and high-dose inhaled corticosteroids [124,125]. Compared with sodium cromoglycate, the evidence suggests that it is at least as good, or even superior, in the treatment of adult chronic asthmatics [126–128]. Like sodium cromoglycate it has no role in the treatment of severe acute asthma.

##### $H_1$ -receptor antagonists

Although effective in the treatment of allergic rhinitis, antihistamines have little place in the treatment of asthma. The evidence for and against the use of these drugs in asthma has been extensively reviewed and it is apparent that the few patients who may benefit from these compounds are young atopic individuals with mild seasonal symptoms [129].

Ketotifen is a commonly used drug, especially in under-developed countries. It is a non-competitive  $H_1$ -receptor antagonist and *in vitro* has an inhibitory effect on mast cells similar to that of sodium cromoglycate. In challenge studies ketotifen has an immediate bronchoprotective effect, although there are no convincing clinical trial data to confirm its value in the long-term treatment of asthma. Like many of the early antihistamines, the most common side-effect of ketotifen is drowsiness, which occurs in over 20% of patients [129].

### Inhaled corticosteroids

Corticosteroids have been used in the treatment of asthma for nearly half a century [130,131]. The early treatment of both acute and chronic asthma was with adrenocorticotrophin (ACTH). However, following the development of a number of glucocorticosteroids, prednisolone became the standard oral therapy, and hydrocortisone and methylprednisolone have become established as the most commonly chosen corticosteroids for intravenous administration. The treatment of asthma with systemic corticosteroids in sufficiently high doses to control symptoms led to the development in many patients of numerous adverse effects, which ironically were all outside the respiratory tract. This stimulated the pharmaceutical search for a drug that was locally active in the control of asthma when inhaled but not absorbed from the lungs or gastrointestinal tract in sufficient quantities to have the same degree of systemic side-effects. The breakthrough came in the early 1970s when beclomethasone dipropionate and betamethasone valerate were found to have high topical activity in the bronchi with low systemic availability. Very soon after this, triamcinolone acetonide and flunisolide were found to possess similar pharmacokinetic profiles, and almost a decade later budesonide was introduced as a corticosteroid with a higher topical activity than those already established in the treatment of chronic asthma. Recently, approximately a decade further on, fluticasone propionate was marketed as a more potent drug than budesonide. The role of this drug has yet to be established since it appears to have greater topical activity than budesonide in terms of control of asthmatic symptoms, but may also have greater systemic activity when absorbed from the lungs.

There can be no doubt that the development of inhaled corticosteroids revolutionized asthma therapy. In the early 1970s there were enthusiastic reports of the efficacy of inhaled corticosteroids assessed in uncontrolled studies [132,133], followed by confirmation of efficacy by the publication of the results of well-designed placebo-controlled studies [134–136]. These showed that withdrawal of oral prednisolone and substitution with an inhaled corticosteroid did not result in poorer control of asthmatic symptoms but did allow worsening of atopic nasal and skin problems, thus confirming the topical, rather than systemic, activity of inhaled corticosteroid therapy. Beclomethasone dipropionate was first introduced into clinical practice in a recommended dose of 400 µg daily (100 µg four times daily). The careful controlled clinical trials in which this drug was substituted for oral prednisolone indicated that this four-times-daily dose of beclomethasone dipropionate, and also betamethasone valerate, was equivalent to 7 or 8 mg of prednisolone [137]. The introduction of topical inhaled corticosteroid therapy thus allowed withdrawal of systemic corticosteroid

therapy in the majority of patients previously treated with these drugs and allowed a considerable reduction in dose in those patients with very severe disease requiring treatment with high doses of prednisolone.

Inhaled glucocorticosteroids have now become first-line therapy for the treatment of chronic asthma in most countries. They are the most effective therapy available and have been shown to have beneficial effects on bronchial wall inflammation and airway hyperresponsiveness as well as symptoms. Bronchial biopsies of patients being treated with inhaled corticosteroids have shown a reduction in the number and activation of inflammatory cells in the airway [138–141] and also restoration of the disrupted epithelium and normalization of the ratio of ciliated cells to goblet cells [138]. Inhaled corticosteroids reduce airway responsiveness to both direct and indirect stimuli. In acute challenge studies, the late response to allergen and the accompanying increase in airway responsiveness is reduced [142] and prolonged therapy protects against the early asthmatic response [143]. A single dose of inhaled corticosteroid fails to protect against exercise-induced asthma, but more prolonged therapy does [144,145]. Chronic treatment reduces airway responsiveness to inhaled histamine and methacholine, although this may take up to 3 months or even longer [143,145–150]. Corticosteroids presumably improve airway responsiveness by reducing the underlying inflammation, although any component of the airways disease caused by structural changes in the bronchial wall, such as thickening of the basement membrane and airway muscle hypertrophy, may be irreversible. Indeed there is now evidence which suggests that if inhaled corticosteroid therapy for asthma is delayed the response, as judged by objective measurements of pulmonary function, is less good than when this treatment is given quickly after the diagnosis has been made [151–153]. It has not yet been established whether prolonged therapy with inhaled corticosteroids can overcome this problem, or whether this indicates irreversible bronchial wall changes that cannot be remodelled. One study showed that there was no 'catch up' in the delayed treatment group after 1 year [151]. These findings have led to the concept of early intervention with inhaled corticosteroids in the treatment of asthma.

Numerous controlled clinical trials have now established that corticosteroids are effective in controlling symptoms of asthma and in reducing the number and severity of exacerbations. This proven efficacy of inhaled corticosteroids, coupled with our knowledge that inflammation is found even in patients with very mild asthma, has indeed led to the use of these drugs at a much earlier stage in treatment [154]. A low dose of an inhaled corticosteroid (e.g. budesonide 200 µg daily) is effective in mild asthma [155], as is once-daily therapy [156]. The various guidelines for asthma therapy recommend this form of treatment for any patient symptomatic enough to require

the use of a bronchodilator inhaler more than once daily [1,55,157].

High-dose inhaled corticosteroid is now frequently used in many countries for treatment of patients with more severe disease [158]. This significantly reduces the need for maintenance oral corticosteroids, and many patients with 'difficult to control' chronic asthma have benefited from this treatment [158–161], although the value of high-dose compared with low-dose therapy has been questioned [162]. Inhaled corticosteroids are effective in the treatment of asthma because they control bronchial wall inflammation, although this may take many weeks to be achieved [138]. When treatment is withdrawn, there is usually an increase in airway responsiveness and recurrence of symptoms to pretreatment levels presumably because of recurrence of bronchial inflammation [147,163–165]. The longer treatment is given, the more likely the possibility of a prolonged remission; indeed, the ultimate aim of treatment is the induction of a complete remission by inhibition of the inflammatory process, or of prolonged remissions by intermittent courses of therapy. A clinically worthwhile prolonged remission is more likely in mild asthmatics treated soon after the onset of their disease. Early treatment is also important since it has been shown that objective response to inhaled corticosteroid therapy is significantly better in patients treated soon after the onset of symptoms compared with treatment delayed by 2 years or more [151–153]. The evidence that there is a better objective response when inhaled corticosteroids are given early after the onset of asthmatic symptoms suggests that irreversible and permanent pathological changes, possibly fibrosis in the bronchial wall, occur at an early stage even in patients with mild asthma. Theoretically this treatment should reduce the irreversible component of airway narrowing seen in patients with more severe poorly controlled disease [166–168]. Whether inhaled corticosteroids reduce the mortality from asthma remains to be demonstrated. The Saskatchewan study of asthma deaths and near-death attacks [169] suggested that this therapy does have this effect, although the numbers studied were too small to reach a firm conclusion.

Although most patients with asthma respond to corticosteroids, there is a small minority who appear to be resistant or much less responsive to these drugs. Disease of this type has been called steroid-resistant asthma [170]. This problem is not explained by pharmacokinetic abnormalities such as impaired absorption or rapid elimination of oral corticosteroids. Compared with normal individuals and corticosteroid-sensitive asthmatics, these patients have been found to have a significantly different response to beclomethasone dipropionate applied to their skin [171], suggesting that this phenomenon is not organ-specific. Corticosteroid-resistant asthma can be defined as a less than 15% improvement in forced expiratory

volume in 1 s (FEV<sub>1</sub>) or PEF to treatment with oral prednisolone in a daily dose of 40 mg given for a period of at least 2 weeks in a patient in whom all other exacerbating asthma factors have been excluded or removed. Patients with asthma resistant to the beneficial effects of corticosteroids have been the focus of much *in vitro* research and abnormalities of peripheral blood cell behaviour have been detected [172]. It is anticipated that if the crucial defect in these patients can be determined, this will lead to the discovery of how corticosteroids exert their beneficial effects in asthma and thus to a focused approach in searching for a cure of this common disease. Corticosteroid-resistant asthma has been comprehensively reviewed [172].

### *Local side-effects*

The most frequent side-effects of inhaled corticosteroids are local effects on the upper airways caused directly by oropharyngeal deposition; these are discussed below.

### *Oropharyngeal candidiasis*

The reported incidence of oropharyngeal candidiasis has varied greatly (5–77%) because of the different criteria used for diagnosis, ranging from a throat swab positive on culture for *Candida albicans* to clinical thrush requiring treatment, and also whether cross-sectional or cumulative analyses have been made [173–177]. Oropharyngeal candidiasis is much less common in children than it is in adults [178,179]. The incidence of thrush is related to the daily dose of inhaled corticosteroid and possibly also to dosing frequency [177,180,181]. The combined use of oral and inhaled corticosteroids does not appear to increase the incidence of candidiasis [173,174,181]. The use of large-volume spacer attachments to the conventional MDI appears to offer some protection against the development of thrush [182,183]. Oropharyngeal candidiasis tends to develop more readily in patients who have a positive *C. albicans* throat swab [184] but is seldom a major clinical problem, can usually be controlled with topical treatment using nystatin or amphotericin, and rarely necessitates withdrawal of inhaled corticosteroid therapy [185]. Oesophageal candidiasis is a very rare complication of inhaled corticosteroid therapy [186]. Candidiasis of the lower respiratory tract has not been reported to have been caused by inhaled corticosteroid treatment.

### *Dysphonia*

Dysphonia or hoarseness of the voice is a much more common problem than candidiasis in patients being treated with inhaled corticosteroids. It occurs to some degree in one-third to half of patients [177,187] and has been reported to be due to a local corticosteroid myopathy

of the vocal cord muscles, which is reversible after withdrawal of treatment [188] but which, unlike thrush, tends to recur when treatment is restarted [189]. The occurrence of dysphonia is related to the total daily dose of inhaled corticosteroid but not to dose frequency [177,187]. Large-volume spacers do not provide any protection against the development of voice problems [180,187], since they increase rather than decrease drug deposition in the region of the larynx and could therefore theoretically make the problem worse. There is some evidence that dry powder inhalers (DPIs) cause fewer voice problems than conventional pressurized MDIs with or without spacer attachments [190,191].

#### *Cough and throat irritation*

Cough and non-specific throat irritation are also common complaints of patients using inhaled corticosteroids [187]. Corticosteroid inhaler-induced cough is much more common with pressurized MDIs than with DPIs and is more often caused by the additives in the inhaler, such as surfactants, rather than the drugs [192,193]. Inhaler-induced cough is often associated with bronchoconstriction [192,194] and pressurized aerosol inhalers should be changed to dry powder systems whenever patients have this problem [193]. Non-specific throat irritation is quite common in patients being treated with inhaled corticosteroids [187], although this is rarely of more than nuisance value and tends to be less of a problem when DPIs are used.

#### *Other local side-effects*

There is no evidence to suggest an increase in infections, including tuberculosis, of the lower respiratory tract after prolonged use of inhaled corticosteroids [178,179], and this treatment does not adversely influence pre-existing colonization of the bronchi with *Aspergillus fumigatus* in patients with allergic bronchopulmonary aspergillosis [195]; indeed it is useful in the long-term management of this condition [196]. Biopsy studies have failed to demonstrate any bronchial mucosal abnormalities, even after treatment for over 10 years [138,197].

#### *Systemic side-effects*

Inhaled corticosteroid treatment was first introduced in a recommended dose of 100 µg four times daily. Subsequently it was found that a dose regimen of 200 µg twice daily was as effective as administration four times daily in maintaining control of chronic asthma. In low doses of up to 400 µg daily it is possible to detect evidence of systemic absorption and activity by assessment of hypothalamic–pituitary–adrenal (HPA) axis function [198], although these minor changes are of no clinical

importance even after prolonged therapy [178]. Indeed the lack of systemic activity allows recurrence of disorders such as eczema and allergic rhinitis when beclomethasone dipropionate or betamethasone valerate is substituted for oral steroids in atopic asthmatics. Despite initial fears regarding the potential side-effects of long-term inhaled corticosteroids, only the minor local upper respiratory problems of oropharyngeal candidiasis and dysphonia have occurred [178].

In recent years, however, much larger doses of inhaled corticosteroids have been used in the treatment of asthmatic patients whose symptoms are not controlled by low-dose therapy, and high doses of these drugs are inevitably associated with systemic effects. These arise from absorption of drug from the lung and the gastrointestinal tract. Adverse effects from swallowed drug depend upon first-pass liver metabolism. Budesonide is more efficiently inactivated by the liver than is beclomethasone dipropionate. The recently introduced fluticasone propionate is almost completely inactivated by the liver when ingested [199] but, like all corticosteroids clinically effective in the treatment of asthma by the inhaled route, gives rise to systemic effects from the fraction deposited in the lung. This is because drug reaching the lung is very rapidly absorbed without metabolism and is consequently available for systemic activity [200]. Therefore, all inhaled corticosteroid preparations in clinical use give rise to systemic effects if high enough doses are inhaled. The differentiation between 'low-dose' and 'high-dose' therapy is now generally accepted. In effect this separates therapy assumed to be safe (low dose) and free from systemic effects from high-dose therapy that might be associated with unwanted systemic corticosteroid effects if given long term. However, the advantages and disadvantages of long-term low-dose and high-dose inhaled corticosteroid therapy are somewhat controversial [201]. It is generally accepted that in adults total daily doses of beclomethasone dipropionate or budesonide up to and including 800 µg are safe and are defined as 'low dose', while 'high-dose' therapy is 800–2000 µg daily [1]. Long-term treatment with doses in excess of 2000 µg (or 1000 µg of fluticasone propionate) should be assumed to be able to cause systemic adverse effects in some of the patients. However, it must be emphasized that, in the main, the amount of drug absorbed from the lung determines the magnitude of systemic activity, and the pulmonary deposition efficiency of different inhalation delivery systems varies considerably. Hence, it is inappropriate to assume that the nominal doses of different inhalers achieve similar therapeutic and adverse effects. Thus, a clinically very effective inhaler must also be expected to have a higher systemic effect than a device that achieves a lower pulmonary deposition [154]. There is a great need for the equivalence of inhaled drugs to be assessed in order to lessen the confusion in this important area of asthma management [202,203].

*HPA axis function*

A large number of studies have assessed the effects of inhaled corticosteroids on HPA axis function. Researchers have focused on the HPA axis because assessments of its function are very much more simple to make than any other estimation of the systemic activity of corticosteroid treatment. However, it is not possible to use HPA axis function abnormalities induced by exogenous corticosteroid treatment to assess the risk of other adverse effects of long-term treatment, such as osteoporosis. Few studies have compared the effects on HPA axis function of the various inhaled corticosteroid preparations available for clinical use, and the findings of these studies are conflicting [154]. However, as one would expect, there appears to be a dose-dependent effect and it has to be assumed that the risk of all systemic adverse effects is dose dependent. Undoubted improvement in HPA function has been established when oral corticosteroid therapy has been replaced by inhaled treatment with beclomethasone dipropionate or budesonide in doses of up to 2000 µg daily [204–206]. Considering all the published data on beclomethasone dipropionate and budesonide and HPA axis function, it can be assumed that clinically significant HPA suppression is unlikely to occur with daily doses up to and including 1500 µg in adults and 400–800 µg in children [154].

*Osteoporosis*

One of the most feared unwanted effects of systemic corticosteroids is osteoporosis [207]. Although low-dose inhaled therapy in adults has been proved to be safe (except perhaps in patients who have received oral corticosteroid treatment prior to substitution with inhaled drugs), the recent increased use of inhaled drugs in high dose has given rise to some doubt about its effect upon bone metabolism. The effects of inhaled corticosteroids on biochemical markers of bone metabolism, such as bone-specific serum alkaline phosphatase, serum osteocalcin, urinary hydroxyproline, calcium and pyridinium cross-links, have been assessed in many short-term studies, even though the relevance of these markers to the risk of development of osteoporosis in the distant future is far from clear. The results of long-term studies of bone density in patients being treated with different doses of different inhaled corticosteroids will have to be awaited before any conclusions about the risks of high-dose therapy and osteoporosis can be made. Clinical trial data so far available raise the possibility of clinically significant osteoporosis developing as a result of long-term high-dose inhaled corticosteroid treatment, although skeletal fracture has not yet been reported as a direct result of such treatment [154]. Those patients at greatest risk are postmenopausal women, the inactive and smokers.

*Growth in children*

Knemometry studies have made it possible to measure accurately linear growth velocity of the lower leg over short periods of time. However, the relationship of this measurement to long-term statural growth has not been determined. However, knemometry is a sensitive method of assessing systemic activity of corticosteroid treatments. It has been shown that budesonide delivered via a large-volume spacer in a dose of 400 µg does not adversely affect lower leg growth velocity [208–210]. Knemometry is extremely sensitive since it has been found that prednisolone in the small dose of 2.5 mg totally suppresses short-term lower leg growth [211]. However, this emphasizes the fact that knemometry is not a measurement of statural growth since although small doses of prednisolone may suppress growth, complete suppression is unlikely. Long-term treatment with budesonide in doses of 400–800 µg daily does not suppress statural growth in children [152].

*Other systemic effects*

The increased risk of the development of subcapsular cataracts in patients being treated with systemic corticosteroids is well known, although despite isolated reports there is no convincing evidence that inhaled corticosteroids cause cataracts in adults or children [154]. Similarly, although minor metabolic effects can be detected, there is no evidence that inhaled corticosteroids result in clinically significant changes in glucose or lipid metabolism.

**Leukotriene antagonists**

Several orally administered leukotriene antagonists have recently been released on the market, and it is likely that other variants will soon be available. It is possible that they may have a role in the treatment of mild asthma or as corticosteroid-sparing drugs, although it is premature to assess their therapeutic role or safety in long-term use. Their actions are considered in Chapter 9.

**Systemic corticosteroids**

Corticosteroids are used in asthma on account of their anti-inflammatory properties, and it is unfortunate that no drug has yet been synthesized that separates these from the metabolic effects responsible for many of their side-effects. The drugs act in a common way. Steroids diffuse through the cell membrane and bind to intracytoplasmic (rather than membrane) receptors. The steroid–receptor complex binds with nuclear chromatin, inducing the production of an mRNA that promotes the synthesis of an effector protein responsible for the steroid

actions. The anti-inflammatory actions include reduction in permeability and dilatation of blood vessels and suppression of accumulation of neutrophils; other effects include reduction in the numbers of circulating monocytes, eosinophils and basophils and extravascular sequestration of lymphocytes, together with inhibition of fibroblast proliferation. Steroids are considered in more detail in Chapter 9.

Oral corticosteroids, usually prednisolone, are the mainstay for aborting and treating acute exacerbations of asthma. Most patients who have suffered a severe attack can recognize the early signs, especially increasing tightness in the chest and failure to respond other than partially to their usual bronchodilator. Such patients should be provided with a supply of prednisolone and told to take it as soon as they realize an attack is starting. The dose may be judged on the patient's size and experience of previous attacks, although it is the author's practice to advise 30–60 mg daily until the chest feels normal, then reducing by 5 mg daily. This is discussed further in the section on acute exacerbations.

Oral corticosteroids are also necessary for the long-term management of patients with chronic asthma. Attempts should always be made to avoid this by maximizing other treatment and by using short intermittent courses, but in some patients control is impossible without regular prednisolone. When this is necessary, the dose should be kept as low as possible and periodic attempts should be made to wean the patient from the drug. The patient should be given a 'steroid card', on which is recorded the dose, duration of treatment, name and telephone number of the doctor and a brief list of emergency instructions. In many subjects this form of treatment is far from satisfactory, requiring as it does a balance between acceptable control of the disease and limitation of side-effects. Hospital asthma clinics are unfortunately full of patients with steroid facies, cataracts, osteoporotic vertebral crush fractures, bruised fragile skin, hypertension and diabetes; some alternative to this treatment is therefore highly desirable.

Parenteral hydrocortisone is used primarily in the management of the acute severe attack. The drug takes at least several hours to have a measurable effect on the airways, presumably depending on the severity of the mucosal inflammation and plugging of the lumen. Depending on an assessment of the severity of the condition at presentation, the dose varies from 100 mg to as high as 1 g. This is usually then repeated either in a constant infusion or as 6-hourly pulses until recovery occurs. This is discussed further in the section on acute severe asthma.

Other uses of parenteral steroids are in the occasional management of chronic severe asthma and patients incapable of taking their medicines reliably (see below). In addition, intermittent injections of ACTH have been used in the management of severe childhood asthma in the hope of avoiding long-term adrenal suppression.

Fortunately the need for this therapy has been much reduced by the advent of cromoglycate and inhaled corticosteroids.

As stated above, patients on long-term steroids should be maintained on the smallest dose consistent with proper control of the asthma. This is judged from the history of symptoms and from regular assessment of PEF or FEV<sub>1</sub>, and no attempt should be made to wean patients from steroids without such careful monitoring. If it seems possible that a patient will manage without long-term steroids, the daily dose should be reduced very gradually (by 1 mg prednisolone each week) and adrenal function assessed periodically by short Synacthen tests. If the patient is successfully weaned from the drugs, he or she should be warned of possible adrenal hypofunction at times of future stress (e.g. operations) and should be told that future acute attacks of asthma will undoubtedly require short courses of steroids. Such patients are understandably reluctant to restart these drugs, and tragic deaths have occurred as a consequence.

In order to prevent the major side-effects of long-term treatment, patients with a history of indigestion should have concomitant therapy with an H<sub>2</sub> antagonist and considered for eradication therapy if there is evidence of *Helicobacter pylori* infection. Postmenopausal women should be encouraged to keep physically active and considered for hormone replacement therapy or other measures to prevent osteoporosis (discussed in Chapter 9).

### General principles of drug use in the treatment of chronic asthma

The principles of management are based on the guidelines produced by the British Thoracic Society [1], the International Consensus Report on the Diagnosis and Management of Asthma [55] and Australian guidelines [63].

The stepwise approach to the treatment of asthma is based on the use of corticosteroids. It is now common practice to use long-acting  $\beta_2$  agonists at an earlier stage than step 3 or 4, although it is accepted that they should always be used in combination with an inhaled corticosteroid. A rare exception to this would be the patient with severe dysphonia or, if less serious, interfering with their occupation, for example a professional singer. The initial management of asthma should be based on the principal aim of achieving optimal lung function and symptom control as quickly as possible initially, and subsequently deciding on the therapy required to maintain symptom control. On many occasions this would require the use of oral prednisolone or high-dose inhaled corticosteroid treatment initially with a subsequent titrated step-down thereafter according to symptoms and PEF recordings. PEF monitoring is essential in the early management of asthma especially when prednisolone or high-dose

inhaled corticosteroid therapy is being used to achieve optimal asthma control.

### Step 1

Occasional use of inhaled short-acting  $\beta_2$ -agonist bronchodilators. If more than occasional use (more than once daily or three times each week) is necessary, treatment with inhaled drugs that have a beneficial effect on the underlying asthmatic inflammatory process should be prescribed (Step 2 treatment). Treatment with an inhaled  $\beta_2$  agonist alone is recommended if it is only used occasionally by a patient with mild asthma who is leading a normal active life and who is free from nocturnal and exercise-induced symptoms.

### Step 2

Regular inhaled corticosteroid in a low dose of up to 800  $\mu\text{g}$  daily (or 400  $\mu\text{g}$  of fluticasone propionate) together with an inhaled  $\beta_2$  agonist to be used as required. Alternatively, sodium cromoglycate or nedocromil sodium can be used instead of an inhaled corticosteroid, although these drugs are rarely as effective. Sodium cromoglycate is mainly used in the treatment of asthma in childhood.

### Step 3

Inhaled short-acting  $\beta_2$  agonist as required plus an inhaled corticosteroid in the dose range 800–2000  $\mu\text{g}$  daily (or 400–1000  $\mu\text{g}$  daily for fluticasone propionate). Large-volume spacers are recommended for use with the conventional pressurized MDI in order to reduce both local and systemic corticosteroid side-effects. The alternative to high-dose inhaled corticosteroid therapy is addition of a long-acting bronchodilator to low-dose inhaled corticosteroid.

### Step 4

Inhaled short-acting  $\beta_2$  agonist as required with an inhaled corticosteroid (800–2000  $\mu\text{g}$  daily) plus a sequential therapeutic trial of one or more of (i) an inhaled long-acting  $\beta_2$  agonist such as salmeterol xinafoate or formoterol, (ii) a sustained-release theophylline, (iii) inhaled ipratropium bromide or oxitropium bromide, (iv) a long-acting oral  $\beta_2$  agonist such as bambuterol, (v) nedocromil sodium or sodium cromoglycate or (vi) high-dose inhaled bronchodilators.

### Step 5

The addition of oral corticosteroid (prednisolone) therapy to high-dose inhaled corticosteroid therapy and the other

drug(s) found to be of benefit during the sequential therapeutic trial in step 4.

### Increasing the dose of inhaled corticosteroid

Doubling the dose of inhaled corticosteroid irrespective of the actual maintenance dose appears to be an effective way of controlling minor exacerbations of asthma. This advice is given to most patients even though there is no clinical trial evidence to prove its effectiveness.

### Short-course oral prednisolone treatment

Short courses of 'rescue' prednisolone are often required to regain control of symptoms during exacerbations. Prednisolone in a dose of 30–40 mg daily can be given to adults until 2 or 3 days after symptom control has been regained. Tapering of the dose is not necessary unless treatment has been required for more than 3 weeks [212].

## Management of severe acute asthma

The clinical features of acute severe asthma are described in Chapter 34. The presentation can range from the moribund patient who has developed respiratory arrest to the apparently distressed breathless asthmatic whose disease is not life-threatening but who is hyperventilating in response to relatively mild airflow obstruction. It is therefore extremely important that an accurate assessment of the degree of severity of the acute episode is made, since the treatment necessary depends on the severity.

### General measures

The majority of patients with severe acute asthma are frightened and distressed by their breathing difficulties, and this may stimulate the uninitiated to attempt relief by the administration of some form of sedative or anxiolytic drug. This is the most culpable mistake that can be made in the management of the distressed asthmatic [213,214]. Sedation must be avoided in all patients outside an intensive care area. Patients suffering a severe acute episode of asthma breathe with maximally efficient use of their respiratory muscles and despite this are unable to maintain normal arterial blood gas tensions. To suppress ventilation with any form of sedation is therefore likely to lead to deterioration. Very occasionally a patient with a mild attack of asthma can become excessively agitated and distressed and this can lead to inappropriate hyperventilation. In this situation the judicious use of a benzodiazepine by the experienced clinician may be of benefit, after the severity of the patient's asthma has been fully assessed objectively. In general terms, however, sedation of any type is contraindicated in severe acute asthma.

Prolonged severe asthma can lead to dehydration

because of lack of intake coupled with an increase in obligatory fluid loss. While intravenous replacement is rarely necessary, it is wise to have an intravenous access in all sick patients, the main purpose of this being to provide a route for drug administration should this become necessary, perhaps unexpectedly.

Electrolyte imbalance is theoretically possible in many patients because of side-effects of drug therapy but, like dehydration, is rarely a clinically significant problem. In particular, hypokalaemia should always be kept in mind since this can be induced by  $\beta_2$ -agonist and corticosteroid therapy in the doses used to treat some patients with severe acute asthma; this can be made worse by the overzealous use of potassium-free solutions for the treatment of theoretical dehydration or for the delivery of intravenous drugs such as aminophylline.

Physiotherapy is of no benefit in the treatment of the severe acute episode unless the patient also has another condition requiring a physiotherapist's assistance, such as bronchiectasis perhaps as a result of coexisting allergic bronchopulmonary aspergillosis. Even then the physiotherapy used must be gentle since the gymnastic rituals of treatments such as postural drainage are absolutely contraindicated in the distressed asthmatic.

Antibiotic treatment is very rarely necessary in the treatment of severe acute asthma, even though a majority of patients are prescribed an antibiotic such as amoxicillin (amoxycillin). Many exacerbations of asthma are triggered by upper respiratory tract viral infections and this often induces the clinician to prescribe antibiotic treatment. However, antibiotics are rarely necessary even if the patient produces scanty apparently purulent sputum. Bronchoconstriction itself, no matter what has triggered it, causes retention of bronchial secretions that might appear to be purulent, either because of minor bacterial infection or because of the presence of large numbers of eosinophils. In either case, treatment should be aimed at improving bronchoconstriction in order to allow the retained bronchial secretions to expectorated.

### Specific treatment

There is no precise order for listing the essential treatments for severe acute asthma, since in critically ill patients most drugs and oxygen should be given at the same time. In the less severely ill, bronchodilator therapy alone may be the only treatment necessary. However, the majority of patients require a combination of treatments. Assessment of the degree of severity of the episode is essential and response to treatment must be assessed carefully with both clinical and objective measurements. The response to treatment of all patients with severe acute asthma should, when possible, include measurement of arterial blood gases (if abnormal initially) and PEF.

### Oxygen

All dangerously ill patients with severe acute asthma are hypoxaemic, or are capable of suddenly becoming hypoxaemic, and oxygen treatment should therefore be routine. Patients with asthma become hypoxaemic and then hypercapnic because of asphyxia caused by severe airflow obstruction and not because of any pre-existing brainstem abnormality of response to oxygen or carbon dioxide (unlike the patient with severe chronic obstructive pulmonary disease). Oxygen should therefore be given by face mask in high concentration, and should only be adjusted according to  $P_{aO_2}$  measurements irrespective of any degree of carbon dioxide retention and respiratory acidosis. The most severely ill asthmatic, prior to death, has respiratory acidosis because of carbon dioxide retention as a result of alveolar hypoventilation caused by severe diffuse airways narrowing leading to asphyxia. These moribund patients are also hypoxaemic for the same reason (asphyxia) and are in need of treatment with oxygen in high concentrations, which unfortunately they are often denied because of the false assumption that high-concentration oxygen therapy in the presence of carbon dioxide retention in asthmatics is dangerous.

The aim should be to maintain a  $P_{aO_2}$  of at least 9 kPa (70 mmHg) and therefore blood gas monitoring of treatment is essential in all patients whose first blood gas analysis is abnormal. When hypoxaemia persists and hypercapnia worsens despite drug treatment (see below), assisted ventilation may be required. Most distressed asthmatics dislike closely fitting face masks and should be treated with masks designed to use the Venturi principle, or even nasal prongs if face masks cannot be tolerated. Those delivering 35% oxygen should be the ones used in the initial treatment of severe acute asthma, and masks delivering higher oxygen concentrations may be necessary. Oxygen tents may have to be used for the treatment of young children.

The administration of bronchodilator drugs, particularly when given intravenously, can theoretically result in worsening of hypoxaemia [215,216] and it is therefore prudent to administer oxygen before, during and after such treatment. Oxygen should be given in the ambulance during transfer from home to hospital, and general practitioners should be encouraged to give oxygen to sick asthmatics whenever possible.

### $\beta_2$ Agonists

Nebulized administration of  $\beta_2$  agonists has now become established as first-line treatment of severe acute asthma [217]. A large dose of one of these preparations, nebulized in oxygen, is at least as effective as the same drug given intravenously but is associated with less unwanted effects [218–220]. The dose of intravenous salbutamol

required to achieve a better response than nebulized treatment is associated with unacceptable side-effects [221]. However, in one study of the early management of acute severe asthma in children, intravenous salbutamol was found to be more effective than when given by the nebulized route [222]. In most circumstances a combination of nebulized and intravenous administration of the same drug should be avoided; similarly, because of the unpredictable onset of activity of a subcutaneously injected  $\beta_2$  agonist, this route of administration should also be avoided. Large doses of salbutamol (5 mg) or terbutaline (10 mg) should be nebulized as initial treatment, since the actual amount of drug reaching the bronchi is unpredictable. In patients who have the most severe airflow obstruction, the amount of drug reaching their bronchi is likely to be less than in those with less severe disease and it is therefore illogical to give all patients the same dose of inhaled  $\beta_2$  agonist. The dose and frequency of administration should be tailored to disease severity and adherence to a strict drug-dose protocol must be avoided. Indeed, continuous nebulization may be successful in patients in whom repeated single treatments have failed [223]. Treatment with a nebulized  $\beta_2$  agonist is unlikely to result in worsening of hypoxaemia [224], but oxygen therapy should not be interrupted during treatment of the hypoxaemic patient. Therefore ultrasonic nebulizers and air compressors driving jet nebulizers should not be used in hospitals for the treatment of severe acute asthma. Aerosol therapy delivered by intermittent positive-pressure breathing has no advantages over simple jet nebulizer treatment [225]. The response to a large dose of a nebulized  $\beta_2$  agonist is rapid, and continued improvement of ventilatory function should not be expected to occur for more than 10–20 min [224,225]. Hence, if a patient remains unwell 10–20 min after this treatment, it should be repeated, possibly in combination with ipratropium bromide; in the very ill asthmatic, intravenous aminophylline should also be considered.

Large-volume spacers designed for use with the conventional MDI provide an alternative to the jet nebulizer for administration of large doses of  $\beta_2$  agonists in the treatment of severe acute asthma [226]. Spacer devices can be used for the treatment of severe acute asthma outside hospital. Face masks allow young children to use large-volume spacers.

Occasionally it is necessary to give therapy intravenously. Salbutamol (4  $\mu$ g/kg) or terbutaline (250–500  $\mu$ g) can be given by slow intravenous injection and also by continuous intravenous infusion.

### Anticholinergic agents

The quaternary ammonium compound ipratropium bromide is of limited therapeutic value in the treatment of chronic asthma but has an important role in the manage-

ment of severe acute asthma. The onset of bronchodilator action of this drug is considerably slower than that of an inhaled  $\beta_2$  agonist but it is as effective as salbutamol [227,228]. Because of the slow onset of action of ipratropium bromide it should not be used alone as primary treatment of a severe attack; when used in conjunction with a  $\beta_2$  agonist, there is evidence that this combination is at least as good as, or better than, either drug given alone [227–231]. The value of this combination therapy has been questioned [232–234], although its use is recommended for patients whose asthma does not respond well to initial treatment with a nebulized  $\beta_2$  agonist [1]. The dose of ipratropium most commonly used is 0.5 mg and there does not appear to be additional benefit if the dose is increased [235]. There are no data available to indicate how long ipratropium bromide should be continued in the treatment of severe acute asthma. However, it is unlikely that it needs to be used for more than 24 h in patients who respond satisfactorily to conventional therapy in the first few hours. Ipratropium bromide is usually given regularly every 4–6 h in combination with salbutamol or terbutaline.

### Xanthine derivatives

Aminophylline has been used for many years in the treatment of severe acute asthma. However, nebulized  $\beta_2$ -agonist therapy has replaced intravenous theophyllines as first-line treatment of severe asthma for reasons of efficacy and safety. Aminophylline is of value in the moribund asthmatic and in the less severely ill patient who does not respond rapidly to treatment with oxygen, parenteral corticosteroids and nebulized bronchodilator therapy. An aminophylline infusion is recommended in a dose of 0.5–0.9 mg/kg/h, or 750 mg over 24 h in small patients and 1500 mg over 24 h in large individuals if the weight of the patient is unknown [1]. In the very severely ill patient a loading dose may be necessary (250 mg by slow intravenous injection, preferably over 20 min), although this should be avoided in the patient known to be taking an oral theophylline preparation. Lower doses may be needed in patients with liver or heart disease and in those taking cimetidine and most quinolone and macrolide antibiotics. Higher doses may be appropriate in smokers. If intravenous aminophylline therapy is necessary for more than a few hours, the dose should be adjusted according to theophylline blood levels.

### Corticosteroids

The value of corticosteroid therapy in the management of severe asthma was first reported in 1949 [236] and confirmed by clinical trial in 1956 [237]. The value of these drugs in the treatment of the severely ill asthmatic has rarely been questioned [238] and their use should be

routine in all patients who do not rapidly respond fully to bronchodilator therapy [239,240]. Large doses of intravenous hydrocortisone or methylprednisolone are usually given empirically since short-course high-dose systemic corticosteroid therapy is rarely responsible for adverse effects, except in the diabetic or patient with cardiac failure. Very high doses of these drugs are probably not necessary [241,242] and might occasionally give rise to an acute steroid myopathy [243]. Occasionally, patients on such doses also develop steroid psychosis, requiring rapid reduction of the dose. Doses of hydrocortisone producing blood levels that exceed stress-induced physiological levels have been recommended [244], i.e. 3–4 mg/kg loading dose followed by the same dose by intravenous infusion every 6 h. However, standard empirical doses of 100 or 200 mg every 4–6 h are used most frequently, intravenous therapy being rapidly replaced with prednisolone in doses of 40 or 60 mg daily. Oral prednisolone is usually given immediately at the same time as hydrocortisone and may be as effective as intravenous therapy in all but the most extremely ill patients [245].

### Assisted ventilation

Assisted mechanical ventilation is rarely necessary but has to be used as a life-saving procedure in some patients who are either moribund on admission to hospital or deteriorate even though they have been treated as outlined above. The indications for assisted ventilation are difficult to define, since they range from the elective decision to ventilate because of lack of response to standard treatment in a patient who is becoming exhausted to the acute emergency resuscitation of the patient who has had a respiratory arrest. The generally accepted indications for the institution of mechanical ventilation include:

- 1  $P_{aCO_2}$  of more than 6.6 kPa (50 mmHg) and rising;
- 2  $P_{aO_2}$  of less than 6.6 kPa (50 mmHg) and falling;
- 3 pH of 7.3 or less and falling;
- 4 intolerable respiratory distress;
- 5 exhaustion because of lack of response to conventional treatment;
- 6 respiratory arrest;
- 7 cardiorespiratory arrest.

The clinically dramatic indications for assisted ventilation in asthma, such as respiratory arrest, are obvious, although mechanical assistance of breathing should also be considered in the less obvious emergency. Physical exhaustion, especially when associated with systemic hypotension, is a dangerous combination and when there is any doubt about the necessity for assisted ventilation the safest course of action must be to ventilate rather than to procrastinate. When a patient with severe asthma has to be ventilated, there is some controversy about the method of assisted ventilation that should be employed. The use of high inflation pressures can theoretically cause baro-

trauma, and the use of controlled hypoventilation carries the risks of prolonged assisted mechanical ventilation [246–249]. The debate about the advantages and disadvantages of adopting policies of planned hypoventilation or the more aggressive approach of trying to normalize arterial blood gas tensions as quickly as possible will continue, and the decisions will depend upon local expertise and facilities available. However, there appears to be no doubt about the dangers of therapeutic lavage of asthmatic patients requiring assisted ventilation [250].

### Inhalation delivery systems

Inhaled remedies have been used for centuries in the treatment of respiratory disorders and bronchodilator aerosols have been used for the treatment of asthma since at least 1935 [251]. In the early days, a number of ways were used to allow the inhalation of medicaments and aerosol inhalation was achieved by hand-held nebulizers driven by air generated by squeezing a rubber bulb. The conventional pressurized MDI was introduced into clinical practice as long ago as 1956 and its basic design has changed little in the last four decades.

### Pressurized metered-dose inhaler

The pressurized MDI is the most commonly prescribed inhaler. It consists of a canister and a plastic actuator. When the canister is depressed into the actuator a measured amount of aerosol is released, the amount of which is determined by the valve in the actuator into which the canister nozzle is seated. Within the canister is drug either as a suspension or as a solution in volatile propellants under pressure (approximately 303 kPa in the case of chlorofluorocarbon, CFC, propellants). The canister of most inhalers also contains a dispersant or lubricant to ensure accurate dose delivery by the valve during multiple actuations of the inhaler. When the valve is actuated, the propellants and drug leave the inhaler at high velocity. The propellants evaporate very rapidly as soon as they leave the canister and this 'flashing' breaks up the liquid stream into droplets that continue to evaporate as they move away from the valve. Because of the high velocity of the aerosol cloud, together with the anatomical structure of the upper respiratory tract and the physical characteristics of the drug particles, the majority of the drug impacts in the oropharynx even when the pressurized MDI is used efficiently. Less than 25% of drug reaches the lung [252,253].

The most efficient way of using a pressurized MDI is as follows [254].

- 1 Shake the canister thoroughly (after removing the mouthpiece cover).
- 2 Place the mouthpiece of the actuator between the lips.
- 3 Breathe out steadily.

- 4 Release the dose while taking a slow, deep breath in.
- 5 Hold the breath in while counting to 10.

These instructions appear to be simple but many, if not the majority, of adults cannot use a pressurized MDI efficiently if the only instruction they receive is the manufacturer's package insert [255–259]. Also, more than 10% of patients develop an inefficient technique with prolonged use of the pressurized MDI [255,259], the majority of these being those who had some difficulty in using the device when it was first prescribed [260]. The main problem experienced is the coordination of dose release during inspiration [259], although a significant number of patients cannot continue to inhale through the mouth when the propellants are released into the mouth ('cold freon effect') [259]. It is rarely possible to teach these patients how to overcome this problem unless a spacer attachment to the pressurized MDI is used. Young children and the elderly experience the greatest difficulties using the conventional pressurized MDI, and for many of these patients spacers or holding chambers have to be used with the pressurized aerosol or alternative inhalation devices have to be prescribed.

Until recently all pressurized MDIs used CFCs as propellants, but because of the effect of these compounds on the ozone layer 80 nations agreed to ban their use before the beginning of the twenty-first century [261]. In some Western countries this ban was brought forward to 1995, with a temporary exemption for medicinal aerosols. Alternative propellants, such as tetrafluoroethane, have been produced and are now in clinical use or undergoing clinical trials. It is likely that because of the enforced change in the contents of the pressurized MDI brought about by the CFC ban, the opportunity will be taken to change or reduce the amounts of lubricants/surfactants in these inhalers, since these have been shown to produce cough and bronchoconstriction in a high proportion of patients [187,192–194].

### Spacers or holding chambers

The principle behind the use of spacers is the fact that the drug aerosol cloud released from a pressurized MDI remains in suspension for many seconds before it is dispersed by gravity and other factors. Also the droplet size of aerosols is dependent on the distance from the actuator orifice. Experiments with tubes and holding chambers of different sizes led to the discovery that these devices could result in an increase in drug availability to the lungs and at the same time decrease the unwanted drug deposition in the oropharynx [262–264]. Large-volume spacers have proved to be of greater clinical value than small 'tube spacer' devices [263,265,266]. A one-way valve at the mouthpiece of a large-volume spacer enables it to contain the aerosol cloud before inhalation, and this overcomes the problem of coordinating dose-release and inhalation,

which therefore do not have to be synchronized when using spacer systems. The efficiency of spacer devices in terms of increasing pulmonary deposition of drug depends upon many factors, including their size, the presence or absence and characteristics of the one-way valve, the electrostatic charge of the plastics used to manufacture the device and the hygroscopic properties of the drug particles. The amount of drug available from the many different spacer systems varies enormously and it is recommended that each device be evaluated for each drug used [267–271]. Large-volume spacers decrease oropharyngeal deposition of drug and their use is recommended for inhaled corticosteroids in order to decrease systemic side-effects (if they are not inactivated by first-pass liver metabolism when swallowed) and also to minimize the risk of oropharyngeal candidiasis [1,182,272–276]. The use of spacers for inhalation of corticosteroids does not cause too much inconvenience, since most treatment regimens are twice daily, although bulky spacer devices are much less convenient for the 'as-required' use of a bronchodilator. Spacers are now most often used in the treatment of children with asthma. In adults their main use is when corticosteroid therapy via the pressurized MDI has to be taken in high dose [1]. However, they can be used as alternatives to nebulizers in chronic [277,278] and severe [226] asthma. Spacers do not decrease the amount of drug deposited in the region of the larynx and do not protect against dysphonia, the most common local side-effect of inhaled corticosteroids [187,251].

### Breath-actuated metered-dose inhaler

The conventional pressurized MDI has been made easier to use by making it breath-actuated. The canister is completely enclosed within the body of the actuator and, depending on the design, is primed by opening a hinged mouthpiece cover or lifting a latching lever on top of the device. When primed, the valve is actuated by a low inspiratory flow in the region of 30 L/min. These devices are easier to use than the conventional pressurized MDI [279,280] and can be triggered by patients with severe airflow obstruction [281].

### Dry powder inhalers

DPIs depend entirely upon the patient's inspiratory effort and are generally easier to use than the conventional pressurized MDI [260]. The first DPIs to be introduced were single dose (Spinhaler soon followed by the Rotahaler) and had to be reloaded with a cartridge/capsule containing micronized drug in a large particle carrier powder, usually lactose.

The second generation of DPIs carry multiple doses (range 4–200) and are more convenient than single-dose inhalers. The four-dose and eight-dose Diskhalers

have to be reloaded after all the foil blisters on the Rotadisk have been punctured; other devices such as the Accuhaler, which like the Diskhaler uses the aluminium foil blister system, are disposable after its 60 doses have been used. The multidose DPIs that use a drug reservoir from which drug is fed by gravity into the dosing mechanism, such as the Turbuhaler (Turbuhaler in the USA) and Klickhaler, contain up to 200 doses and are discarded when empty.

DPIs are less bulky than spacers and are as easy to use as the breath-actuated pressurized MDI, although some DPIs are less convenient because of the need to reload capsules/cartridges or discs frequently. Clinical comparisons of different DPIs indicate that patients prefer multidose devices to single-dose inhalers [282,283], and a meta-analysis of all available studies showed that 58% of 530 patients preferred a multidose DPI to the pressurized MDI [284]. The major drawback of DPIs is that their efficient use depends upon the patient being able to generate sufficient inspiratory flow to allow the drug to reach the lungs in therapeutic amounts. The various DPIs have vastly different inspiratory resistances, but there have been few comparisons of intrapulmonary drug deposition and clinical efficacy of these devices used at different inspiratory flow rates. This makes it difficult to give informed recommendations about the advantages and disadvantages of the numerous DPIs now available [260]. Children under the age of 6 years may not be able to generate sufficient inspiratory flow to use the Turbuhaler; the younger the child, the more likely this is the case [285]. It is known that the Turbuhaler is less efficient at an inspiratory flow rate of 30 L/min than at 60 L/min [285,286], and the Rotahaler has only about 10% of its maximum bronchodilator effect at inspiratory flow rates of 40 L/min [287]. Until direct comparisons of all DPIs have been made and data about optimal inspiratory flow rates are available, it has to be assumed that, unlike the pressurized MDI, the most efficient way of using a DPI is to breathe in through the device from residual volume as quickly and as deeply as possible. There is a need for more research on DPIs, especially with regard to the proportion of the dose reaching the lung, since this is extremely important when corticosteroid preparations are being inhaled. There is already evidence that the Turbuhaler is twice as efficient as the pressurized MDI for the inhalation of budesonide [288], while another study has suggested that another DPI is only about half as efficient as the pressurized MDI [253]. Immediately after DPIs are used for corticosteroid administration, gargling and mouth rinsing should be advised since this has been shown to decrease systemic effects from drug deposited in the oropharynx [289].

### Nebulizers

Nebulizers are of two types: jet and ultrasonic. Jet nebu-

lizers have widely differing characteristics with regard to the generation of particles within the respirable range [290] and the performance of individual nebulizers is influenced by many factors, such as the flow rate of the driving gas (air or oxygen), the nature of the drug solution or suspension, the fill-volume of the nebulizer chamber and, of course, the nebulization time [290–295]. For basic clinical purposes it is essential to be familiar with the characteristics of one nebulizer system, particularly the flow rate at which it functions most efficiently. For most clinical purposes jet nebulizers are more efficient than ultrasonic nebulizers. An ultrasonic nebulizer should be chosen for the administration of hypertonic saline to induce the production of sputum. For full details concerning the use of nebulizers the publication produced by the British Thoracic Society is recommended [296].

### Immunotherapy

The treatment of asthma by antigen injection goes back to 1911, before its allergic basis was described, and such treatment remains in widespread and often uncritical use in some countries [297]. This continued use without clear evidence of value, together with the success achieved by bronchodilator drugs, has given immunotherapy a reputation of unorthodoxy. Nevertheless, there is evidence of efficacy in certain cases and it would be a pity if further research in this subject were to cease [298,299].

The principle of immunotherapy is to give initially small, then increasing, doses of pure antigen to a patient who is sensitive to that antigen in the hope of producing interference with the IgE-antigen-mediated reaction responsible for the symptoms. Whether this effect, when it occurs, is due to IgG blocking-antibody formation, a decrease in the sensitivity of mast cells to challenge or some other mechanism is not known [300,301]. Success of such therapy might therefore be expected to depend on selection of a patient in whom the symptoms are entirely or very largely due to the antigen in question and on the availability of a sufficiently pure form of the antigen in the vaccine. In keeping with these criteria, there is no evidence of the efficacy of immunotherapy in non-atopic asthma, asthma associated primarily with infection or in asthma with multiple allergic factors. The use of blunderbuss-type vaccines is strongly to be condemned, as is the use of vaccines in circumstances where treatment for anaphylactic reactions is not readily available. Indeed, use of such vaccines outside hospitals has been effectively prohibited in the UK [297].

There is some evidence of efficacy of immunotherapy in the treatment of hay fever and asthma associated with grass pollen and ragweed sensitivity, rhinitis and asthma associated with house-dust mite sensitivity, and similar symptoms related to exposure to cats and laboratory animals [302–308]. However, it has to be admitted that

several equally well-controlled studies have failed to show differences between groups treated with active and placebo preparations, and a strong placebo effect has been present in most investigations [309,310]. It is to be expected that research will lead to the production of increasingly pure vaccines that, in turn, will increase the range of allergies treatable and the overall efficacy of the treatment.

At present, it is recommended that treatment be reserved for those few patients with clear evidence of sensitivity to house-dust mites or grass pollen (or ragweed pollen) in whom drug therapy proves ineffective or unacceptable. Such patients usually have conjunctival and nasal symptoms as well as asthma. Careful explanation of the likely outcome is advisable before starting: it is reasonable to predict an even chance of some improvement and a small chance of a big improvement. Epinephrine (adrenaline) should be available for anaphylaxis and the patient should remain under observation for 2h after the injection, although almost all reactions occur immediately. If the injections cause worsening of the asthma or any other suspicious symptoms, it is very unwise to continue the course. Use of such treatment for other allergic factors in asthma is best confined to allergy specialists engaged in research.

## Miscellaneous problems in asthma management

### Bronchopulmonary aspergillosis

The clinical manifestations of this syndrome vary from asthma associated with very occasional episodes of pulmonary eosinophilia to a severe progressive condition leading to lung fibrosis and bronchiectasis (see Chapter 34). Treatment should be judged by the response of the individual and not on the basis of studies that have shown average effects or lack of effects on groups of patients. Thus it is perfectly possible to maintain patients with milder manifestations on inhaled bronchodilators and inhaled steroids, so long as they are taught to treat exacerbations early with courses of high-dose oral steroids [196]. Asymptomatic episodes of pulmonary eosinophilia do occur in patients not on long-term oral steroids but only very rarely. If these are occurring, they may be detected at annual clinic visits by evidence of radiographic and functional deterioration. Such episodes, or frequent symptomatic attacks, or persistent presence of hyphae in the sputum require long-term oral steroids, again with increase in dose to cover exacerbations. It is in such patients, where the persisting antigenic stimulus due to survival and germination of the fungus in the airways leads to chronic disease, that consideration should be given to eradication of the organism. Newer oral antifungals are available (see Chapter 21) and promising results

have been reported with ketoconazole [311]. In severe cases where there is a risk of high-dose steroids leading to invasive disease, a course of amphotericin should be considered. A patient treated successfully with antifungal drugs would of course still remain sensitized to *A. fumigatus* and therefore liable to an exacerbation next time adequate numbers of spores are present in the air. Trials of pulsed antifungal therapy are ongoing, the aim being to eradicate the fungus with the first treatment and then to prevent recolonization with shorter courses of treatment every few months. The long-term outlook, and the effect of antifungal treatment on it, must therefore remain uncertain, although experience suggests that many such patients can be maintained well and without deterioration in lung function for many years on routine treatment of chronic asthma. It is probable that early diagnosis, before significant lung damage has occurred, is the secret of successful management.

### Pregnancy

Many young female patients with asthma are understandably anxious about the effects of their illness on pregnancy and vice versa. Three problems merit discussion: the effects of asthma on pregnancy, the effects of drugs on the child and the chances of having an asthmatic child. The course of asthma during pregnancy is impossible to predict but usually is no different to that when the patient is not pregnant, improving in a few cases and requiring additional treatment in others [312,313]. It is wise to reassure the patient and to make oneself available for help with attacks should they occur. It is possible that very high steroid doses may have a deleterious effect on the early fetus, although it is likely that a severe asthma attack could have similar consequences. Either or both seem to increase the risk of mild pre-eclampsia [313]. The patient should be encouraged to use steroids in adequate dose early, so as to avoid the large doses that might be required in hospital. The other drugs used in asthma are not known to be toxic to the fetus, although clearly it is wise to confine treatment to inhaled drugs as far as possible except during acute exacerbations. Finally, patients who have had severe asthma are often worried that their children will suffer the same problem. It has to be admitted that this is possible, though the severity of asthma in several affected members is usually very different. There is no good genetic reason for an asthmatic patient to deny herself children.

Having discussed these matters, the management of asthma in pregnancy should be exactly as in the non-pregnant state. Care should be taken to explain this to the patient, who has a natural tendency to withdraw treatment and avoid drugs for the exacerbations that may ensue as a result. As always, time spent explaining this to the patient is time well spent.

## Heart disease

The asthma patient who develops angina or hypertension is at risk of having  $\beta$ -blocking drugs prescribed and thus being made worse, sometimes acutely. Alternatives for hypertension are diuretics, methyldopa, reserpine, captopril, prazosin or nifedipine. For angina, vasodilators such as nitrates, verapamil or nifedipine are acceptable. From the cardiologist's point of view, drugs used in asthma may be undesirable;  $\beta_2$  agonists in high dose may worsen angina and steroids commonly promote fluid retention and hypertension. Judgement is therefore necessary in deciding on an optimal dose.

## Surgery

The majority of patients with asthma have no problems even with thoracic surgery, so long as they, the surgeon and the anaesthetist are adequately prepared. The patient should be treated vigorously for a week or two preopera-

tively in order to achieve normal or near-normal flow rates, and appropriate inhaled medications continued over the postoperative period. Corticosteroid cover should be provided if the patient is likely to have suppressed adrenal function and acute exacerbations of asthma should be treated along routine lines.

## Other problems

An asthmatic on oral corticosteroids who develops tuberculosis and is given rifampicin probably needs to double the dose of steroid to obtain the same effect, because of drug interaction. Senile, psychotic or retarded patients cause particular problems with drug compliance. Treatment should be kept as simple as possible and supervised by a nurse or relative. Those requiring long-term oral steroids may sometimes be most reliably treated with depot injections. Visually impaired patients should be provided with inhalers that have different shapes for different functions.

# REACTIVE AIRWAYS DYSFUNCTION SYNDROME

ANTHONY SEATON

Exposure of the respiratory tract to irritant gases or fumes may lead to one or more of a number of adverse consequences, although in the majority of cases no long-term harm ensues. To some extent, the site of pathological change is determined by the solubility of the gas, in that the most soluble exert their effects proximally in the nose, throat and main airways while the less soluble cause damage more distally in the acinus. These different responses and the agents that most frequently cause them are discussed in Chapter 54 and summarized in Table 36.1. It is important to recognize that in practice such responses may occur in combination and mixed syndromes, not fitting neatly into any one classification, are quite common.

Of all the possible lung responses, the one most frequently seen is an asthmatic type of reaction that has acquired the name of reactive airways dysfunction syndrome (RADS). Asthma has been recognized for many years as an occasional consequence of accidental exposure to high concentrations of airborne irritants, and such exposure was included by Gandevia in 1970 [1] as one of the causes of occupational asthma, although he did not regard this as true asthma. From the late 1970s a series of papers reported the development of asthma after exposure to sulphur dioxide, ammonia and chlorine [2–5], and in 1985 the term RADS was coined to describe the syndrome and to draw attention to it as a response to a wide range of toxic inhalation episodes [6].

## Definition

There is an obvious danger in defining any disease, since it results in an arbitrary cut-off between health and normality in what is often a continuum. It thus leads to exclusion of individuals with obvious ill-health who do not quite fit into the definition. Definition should therefore be specific to the purpose for which it is intended and should not be used for other purposes. When Brooks and colleagues [6] first defined RADS, they correctly indicated the criteria that they had used to identify their cases in

order to clarify their methods for the reader. These criteria were:

- 1 a documented absence of previous respiratory complaints;
- 2 onset of symptoms occurring after a specific exposure incident or accident;
- 3 exposure to a gas, smoke, fume or vapour present in high concentration and with irritant properties;
- 4 onset of symptoms occurring within 24 h of the exposure and persisting for at least 3 months;
- 5 symptoms simulating asthma, with cough, wheeze and dyspnoea;
- 6 pulmonary function tests 'may show airflow obstruction';
- 7 other pulmonary disease ruled out.

Since that time there has been debate about the possibility of RADS occurring after repeated or chronic relatively low exposures [7]; it is also clear that someone with pre-existing asthma or airways disease may worsen after an exposure to irritant chemicals [8]. The above criteria should not therefore be looked upon as a definition of the disease. Rather, it is appropriate to define RADS for clinical purposes simply and broadly as non-allergic asthma occurring following exposure to airborne irritant chemicals. For a discussion of the definition of asthma see Chapter 34.

## Clinical features

In the classical case, a patient who has been well previously is exposed to a spill of irritant chemical, for between seconds and hours, and within the next few days develops cough, wheeze and breathlessness. The symptoms at first are often rather mild and may be dismissed by the patient and doctors as unimportant, but as time goes by they become more rather than less troublesome [6,9]. Cough is often the most prominent symptom and may cause disturbed sleep. The patient usually complains that laughing, raising the voice, exertion and exposure to smoke or strong scents precipitates cough and wheeze. Severe

**Table 36.1** Syndromes associated with exposure to irritant substances.

Site of lesion	Pathological response
Nose	Rhinitis
Larynx	Acute laryngitis, laryngeal oedema
Trachea	Tracheitis
Bronchi	Acute bronchitis, asthma, irritable airways
Bronchioles	Obliterative bronchiolitis
Alveoli	Pulmonary oedema

attacks of asthma may occur, although these are usually confined to the first few weeks after the exposure.

Lung function testing often, though not always, shows a reduction in forced expiratory volume in 1 s (FEV<sub>1</sub>) and an increase in residual volume. The airflow obstruction is usually partially reversible. A methacholine challenge test would be expected to be positive, and this has been viewed by some as a necessity for making the diagnosis [8,10]. In general, diffusing capacity is normal, although different patients may show different patterns of abnormality in keeping with the combination of syndromes that follow toxic gas exposure [11]. The chest radiograph is normal in the absence of pulmonary oedema.

As time passes, personal experience suggests that the majority of patients find their symptoms less troublesome, though adequate follow-up studies unclouded by litigation issues are few. One such study reported the examination and lung function testing of 20 patients up to 12 years after exposure to a spill of chlorine in a pulp mill [12]. All had suffered acute symptoms including dry cough and none had been treated with corticosteroids. In general, they had shown an obstructive pattern of lung function immediately after the episode, with raised residual volume. Thereafter, the FEV<sub>1</sub> improved initially and then showed a slow decline, while the residual volume progressively declined, suggesting that the long-term consequences were not trivial and that some permanent damage to small airways had occurred. In another study of 64 workers exposed repeatedly to chlorine over several months in another pulp mill, 58 had symptoms, 16 airflow obstruction and 29 bronchial hyperreactivity when examined 18–24 months after exposure had ceased [8].

Because of the paucity of good long-term studies, it is necessary to rely on personal experience to comment on the outcome and this is inevitably coloured by one's practice and local referral patterns. The large majority of workers exposed to irritant gases or fumes never present for specialist care and make a full recovery after a few hours or days of coughing and perhaps a visit to the local accident department, as indicated by the relatively small proportion of those subjects reported by occupational

physicians to the SWORD project (see below) who develop asthma [13]. Those seen by a specialist present the more typical features described above and are usually treated for asthma with satisfactory results. They slowly recover and can often stop their medications over the course of a couple of years. However, some present more severe symptoms, never respond adequately to anti-asthma medication and become progressively more breathless with irreversible airflow obstruction; these patients fall into the classification of obliterative bronchiolitis (see Chapter 29). Between the two extremes are a few patients who continue with persistent and typical asthma.

In the author's opinion, the chest physician should keep an open mind about the possibility of a similar syndrome occurring as a response to repeated lower-dose exposures to irritant fumes or gases. Recent studies have confirmed that cigarette smoking is, after a family history of atopic disease, the most important risk factor for adult-onset wheezy illness [14]. It would not be surprising if similar consequences occasionally followed long-term exposure to other irritants, and the author's experience suggests that this is so. Several reports in the literature support this view. For example, Kippen and colleagues [7] described 32 patients seen in an occupational clinic with asthma, of whom seven had classical RADS while 10 had a similar syndrome following low-dose exposure on a frequent basis. Chia and colleagues [15] showed that regular fire-fighters were more likely to show increased airway reactivity after experimental exposure to smoke than were recruits, suggesting that recurrent exposure had rendered them more susceptible. The construction workers described by Bh  rer and colleagues [8] who developed bronchial hyperreactivity from working in a pulp mill gave a history of recurrent exposures to chlorine rather than a single severe exposure. All these examples suggest that increased airway reactivity may follow a wide range of types of airway irritant damage apart from that caused by inhaling tobacco smoke.

## Frequency

The best indication of the frequency of the syndrome to date comes from the UK SWORD project, in which respiratory and occupational physicians report clinical diagnoses of occupational and work-related diseases [16]. Among these are two categories, inhalation accidents and occupational asthma, the latter being divided into allergic and RADS. Approximately 180 inhalation accidents are reported each year, leading to an estimated annual incidence of about 230 [17]. This probably represents a minimum figure, as it is likely to exclude many of those treated by non-respiratory physicians and of those occurring in industries without an occupational physician. One study of these reports has shown that of

623 patients, 50 developed asthma lasting for a month or more [13]. Among 47 of these cases in whom data were available, 34 were confirmed as having developed asthma as a consequence of the exposure. Thus, some 5–6% of people reported as having had an exposure to toxic gases or fumes in the UK seem to develop asthma. In addition, among the reports of occupational asthma, some 15% appear to be ascribed to irritants rather than to allergens, suggesting that around 110 such cases are reported each year. In total, therefore, about 150–200 patients develop asthma severe enough to be reported to the SWORD scheme each year, from a total UK workforce of about 20 million, or 1 per 100 000 per annum. This might be regarded as a minimum incidence of the condition.

In a survey in 1978 by the US Social Security Administration, a question was asked about work-related ill-health. The survey was biased towards people with disabilities. Of the 6000 respondents 7.7% said they had asthma, most of whom reported a physician diagnosis [18]. This prevalence was roughly double that recorded in a contemporary national health survey. Of those with asthma, 15% attributed it to bad working conditions. These would have included many with true allergic occupational asthma but presumably some had asthma due to irritants. If this proportion approximates to that in the SWOKD study, it suggests that some 2 per 1000 respondents might have had RADS. In view of the deliberate bias in sampling towards disabled people, this is a substantial overestimate of the prevalence in the working population. In a survey in the UK in 1990, a random sample of adults in 60 000 households was asked if they had any illness that they related to their work [19]. From the responses it was estimated that about 30 000 people believed that they had work-caused asthma, and on the same 15% basis this suggests that some 5000 may have RADS, or 2–3 per 10 000 of the current workforce.

In practical terms for those who see patients with asthma, it has been reported that of 154 patients referred to an occupational medicine clinic with a possible diagnosis of occupational asthma, the diagnosis was confirmed in 59, in 10 of whom it had been induced by high-dose exposure to irritant chemicals [20]. This experience tallies with that of the SWORD project in suggesting that some one in five or six people with occupational asthma have it as a consequence of exposure to irritants rather than sensitizers.

## Causes

On reading the literature one is struck by the wide range of exposures reported as having led to RADS, and personal experience supports this. In the original paper by Brooks and colleagues [6], the illness was reported after exposure to uranium hexafluoride, floor sealant, ammonia, smoke,

and various fumigating and surface coat-removing substances. The most common reported causes are spills of strong acid and alkali, escape of chlorine and ammonia, and sulphur dioxide. However, any irritant smoke or fume seems able to initiate the process, and it is not uncommon to see patients with it after inadvertent mixing of household cleansing chemicals. Some well-known sensitizers, such as isocyanates, are also irritants in high concentrations and exposures may lead to either RADS or true sensitization [21].

## Pathology

There are few reports of the pathology of RADS. In the original description, bronchial biopsies in two cases showed some epithelial desquamation and primarily lymphocytic inflammation [6]. More recently, Gautrin and colleagues [22] have reported on the bronchial biopsies in five subjects with RADS, in whom they showed focal epithelial desquamation, squamous cell metaplasia, some subepithelial fibrosis, thickening of the basement membrane and mainly lymphocytic inflammation. Bronchoalveolar lavage fluid showed mainly lymphocytes. They considered these changes to be consistent with the generally reduced reversibility and lability of the airflow obstruction in such patients compared to those with sensitization, and therefore concluded that the two types of occupational asthma are pathologically distinct.

## Management

There are no clear guidelines for either acute or long-term management of RADS. Since airway inflammation is the basis of the initial pathological damage, it would seem sensible to treat patients who are symptomatic following acute irritant exposure with high-dose oral corticosteroids. Once RADS has developed, it is usual to treat it along conventional lines for asthma, and partial reversibility is to be expected. Progressive irreversible obstruction suggests obliterative bronchiolitis and in these circumstances high-dose steroids should be continued until it becomes apparent that no benefit is occurring.

In the majority of patients treated personally, slow improvement from RADS has occurred, the need for inhaled steroids and bronchodilators progressively diminishing. Ultimately, most are able to lead a normal life with only intermittent episodes of wheeze provoked by infections or further exposure to irritants. Long-term oral steroids have not been of benefit in either those with RADS or those with obliterative bronchiolitis.

# HYPERSENSITIVITY LUNG DISEASES

ANTHONY SEATON

The history of hypersensitivity lung diseases goes back to 1932, when Campbell [1] described acute respiratory symptoms in farmers after work with hay and Tower and colleagues [2] described similar symptoms in maple bark peelers. The association of the conditions with inhalation of microbial spores was recognized and, in the case of maple bark disease, it was speculated that the pathogenesis might be a form of hypersensitivity reaction to *Cryptostroma corticale*. Farmer's lung was subsequently shown to be due to the inhalation of spores of thermophilic actinomycetes (now classified as bacteria) and of species of *Aspergillus*. The finding of precipitating antibody to such organisms led to the concept that the disease was an example of a pulmonary type 3 allergic reaction, although study of lung biopsies, animal models and bronchoalveolar lavage (BAL) fluid has shown that cell-mediated reactions are also crucial to the development of the condition.

Study of the pathogenesis of farmer's lung led to considerable interest in other possible causes of hypersensitivity pneumonitis; bagassosis had been described (as a bronchiolitis) in 1946 [3] and it became apparent that this disease was similar in aetiology to farmer's lung. The occurrence of similar syndromes in response to animal antigen was recognized when bird fancier's lung was described in 1960 [4,5], while more recently sporadic examples of a similar condition have been described in response to exposure to certain chemicals of relatively low molecular weight [6–8]. A very large number of causes, mostly related to inhalation of fungal spores, have been recorded and undoubtedly more remain to be described.

It is important to recognize that the syndrome of hypersensitivity pneumonitis covers a range of reactions, varying from the classical severe acute episodes of farmer's lung to a much more chronic illness such as occurs most frequently in response to bird antigen. In addition, variations on the theme occur in people exposed to aerosols from air conditioners and humidifiers, to dust in grain silos and to sewage sludge. These other condi-

tions are discussed further in Chapter 54. Moreover, very similar reactions may occur in response to treatment with certain drugs and these are discussed in Chapter 55.

## Clinical features

The classical acute presentation occurs mainly in individuals exposed to high doses of microbial spores, as seen typically in farmers feeding cattle with mouldy hay [9,10]. The onset of symptoms is about 4–9 h after exposure, with chills, dry cough and an influenzal feeling. Rigors may occur and the patient notices breathlessness on normal exertion. Severe attacks may result in profound dyspnoea but in most cases general malaise is the predominant symptom. The main findings on examination are repetitive mid- and late-inspiratory crackles and tachypnoea. Polyphonic wheezes may be heard and should not deter one from making the diagnosis. Precipitating antibodies are commonly found in the blood.

Such acute attacks usually settle after 48 h. However some episodes may be much more persistent and the patient may remain ill and breathless for several weeks. In very rare instances the acute attack may be fatal [11]. Another variant, related to the removal of mouldy grain from the tops of silos prior to emptying the silage, presents with cough, fever, chest tightness, malaise and headache about 2–8 h after exposure [12,13]. Crackles are less frequent and precipitins are absent. This syndrome has been called mycotoxicosis or organic dust toxicity. However, despite differences in immunopathogenesis, its similar aetiological, clinical and pathological features to farmer's lung suggest that it should be regarded as a variant of that form of hypersensitivity pneumonitis.

At the other extreme of the spectrum of clinical presentation is the usual response to budgerigar (parakeet) antigen. Such patients present with insidious malaise, breathlessness, unproductive cough and sometimes loss of weight, often over months or even years [14,15]. Again, repetitive inspiratory crackles are the characteristic physical sign. Polyphonic wheezes may also occur and, in the

more chronic cases, a high-pitched, short, late inspiratory squeak is often heard [16]. This sign, which also occurs in other chronic pulmonary fibroses and in rheumatoid bronchiolitis, usually follows an inspiratory crackle and is probably caused by vibration in the wall of a bronchiole as it opens following abnormal closure. The presence of such signs of airway disease serves as a reminder that so-called allergic alveolitis affects bronchioles as well as alveoli.

A proportion of patients with allergic alveolitis of any sort may progress to a chronic form of the disease, characterized particularly by increasing exertional dyspnoea over years [9,17]. Inspiratory crackles are usually present but some of these patients may develop the clinical, radiological and physiological features of generalized emphysema. Patients with chronic allergic alveolitis may progress to fatal cardiorespiratory failure [11]. Finger clubbing is not a feature at any stage. In contrast, some patients who continue to be exposed to antigen despite medical advice do not progress to chronic disease and may even show evidence of spontaneous desensitization.

In most patients with allergic alveolitis, the most important diagnostic clues come from the history and the finding of inspiratory crackles. Acute episodes bear a clear relationship to exposures to antigen, such as mouldy hay, pigeons or work in maltings. If a more insidious type is suspected, attention should be paid in history-taking to exposure on a regular basis to known causes. Periodicity of symptoms is important; in Japan, *Trichosporon cutaneum* commonly grows in damp wooden houses and sporulates in the warm summer temperatures, causing outbreaks of seasonal alveolitis [18]. Patients with budgerigars improve when they (or the budgerigars) leave home for a while, and work-related symptoms may improve over holidays.

Allergic alveolitis may occur at any age; children who help their parents on farms or in pigeon lofts or who are exposed to antigen in the house may present with the disease. In several surveys cigarette smokers have been shown to be less susceptible than non-smokers [19,20].

## Radiographic features

In acute episodes, the chest radiograph commonly shows a bilateral, diffuse, micronodular infiltrate, usually denser towards the hila (Fig. 37.1). An irregular and linear infiltrate may also be present in the lower zones. In severe attacks it may mimic acute pulmonary oedema, *Mycoplasma* pneumonia or pneumonitis due to inhalation of toxic gases, although it should be noted that in some of the precipitin-negative cases occurring in workers clearing the tops of silos the radiograph remains normal even when the systemic illness is quite severe. The changes usually resolve rapidly on removal from exposure and treatment with corticosteroids. As mentioned above, in

some cases resolution is slow, taking several weeks and giving rise to diagnostic difficulties. If the patient is a farmer, silo-filler's lung (pneumonitis due to nitrogen dioxide) needs to be considered in the differential diagnosis and lung biopsy may be necessary. *Mycoplasma* or other atypical pneumonia may also be confused clinically and radiologically, especially as such patients occasionally produce false-positive precipitating antibody to farmer's lung antigens [21].

In less acute cases, the radiographic signs may be more subtle and sometimes even absent. A very sparse micronodular infiltrate, perhaps indistinguishable from a normal film, should not prevent the diagnosis in the presence of an appropriate history and the finding of inspiratory crackles. Some patients, particularly those with disease related to inhalation of chemicals, may present with dense, patchy consolidation easily confused with an infective pneumonia. The first patient described as having alveolitis due to isocyanates presented in this way [6] (Fig. 37.2).

Chronic allergic alveolitis may progress to pulmonary fibrosis, which characteristically affects upper zones predominantly. Coarse, irregular shadows extend from hila to apices with attendant bronchiectatic change, retraction upwards of pulmonary vessels and, often, well-marked emphysema in the lower zones (Fig. 37.3). In some of these patients the fibrosis may be invisible radiologically, the appearances being indistinguishable from those of cigarette-related emphysema [9]. In the more usual type, the radiological appearances resemble those of old tuberculosis, chronic sarcoidosis, ankylosing spondylitis lung or accelerated silicosis. High-resolution CT may assist in the differential diagnosis by showing a peribronchiolar or centriacinar distribution of nodular change [22].

## Pulmonary function

The typical changes in an acute attack are reductions in lung volumes, carbon monoxide diffusing capacity and  $PO_2$  [9,23]. In milder cases, only a slight fall in diffusing capacity and  $PO_2$  during exercise may be found. If compliance is measured it is found to be decreased, as would be expected. The reduction in diffusing capacity is a more sensitive test of acinar disease than the chest radiograph, and in the more subacute syndromes (e.g. in people exposed to budgerigars) it is often present when the radiograph is normal. Sometimes the patients with the so-called organic dust toxicity syndrome or mycotoxicosis have normal chest films and lung function, showing only slight oxygen desaturation [13].

In most patients with acute episodes the volumes, codiffusion and  $PO_2$  abnormalities recover over a few days or weeks, though increases in diffusing capacity may still occur after a year [24]. However, in those with subacute or chronic disease recovery may be slow and incomplete,

**Fig. 37.1** Diffuse bilateral ground-glass appearance of acute farmer's lung.

**Fig. 37.2** Dense pneumonic infiltrates throughout left lung and in right mid zone. This proved to be an acute hypersensitivity reaction to toluene diisocyanate.

**Fig. 37.3** Irregular upper zone fibrosis in patient with chronic farmer's lung.

leaving the patient with chronic impairment of function. Evidence of airflow obstruction may be present in a number of these patients, not always explicable on the basis of smoking or concomitant asthma [25]. While bronchiolitis is the likely explanation in some, up to one-third of patients with well-developed chronic allergic alveolitis develop a pattern of irreversible airflow obstruction, reduction in diffusing capacity and pathological emphysema [9,26,27].

### Pathology

In keeping with the inhalational route of exposure, the pathological changes in acute allergic alveolitis are most marked at the centre of the acinus and least at the periphery [10,27]. When a biopsy shows non-specific changes, this pattern of distribution may be an important clue as to aetiology. In the very acute cases described as mycotoxicosis, intense inflammatory change with polymorphonuclear leucocytes has been noted in bronchioles [12], although one such patient studied personally has also shown typical non-caseating granulomas. In typical acute cases, the alveolar inflammation extends to the bronchioles where it is somewhat less marked, and is usually characterized by a lymphocytic and granulomatous reaction. Sometimes this may occlude the smallest airways. In

addition, non-caseating granulomas including Langhans-type giant cells, lymphocytes and plasma cells are found predominantly at the centre of the acinus (Fig. 37.4). The alveolar walls are thickened, with oedema and chronic inflammatory cells; foamy macrophages may fill the alveoli. Fibrin deposition may be demonstrated and, depending on the length of the illness, it is not uncommon to see some mature collagen in alveolar walls. In contrast to immune complex disease, vascular changes do not normally occur. In a unique case, a lady with allergic alveolitis due to dust from sea snail shells was shown to have deposition of amyloid in her alveolar septa [28]. Ultrastructural studies show swelling of alveolar epithelial cells and disruption of basement membrane in association with the inflammation [29].

In chronic disease, the granulomatous changes may disappear. The lungs become fibrosed and secondary cystic change due to bronchiolectasis occurs. The fibrosis is usually more marked in upper zones and secondary emphysema is common. Secondary vascular changes reflect the pulmonary hypertension.

### Pathogenesis

Despite its relative rarity and the ease with which the condition may be treated and prevented, the pathogenesis of

**Fig. 37.4** Histological appearances of acute allergic alveolitis: (a) centriacinar distribution of mononuclear cell infiltrate with poorly formed granulomas (haematoxylin & eosin  $\times 25$ ); (b) higher power demonstrating granuloma within the bronchiolar wall as well as the interstitial mononuclear cell infiltrate (haematoxylin & eosin  $\times 115$ )

hypersensitivity pneumonitis has attracted a huge amount of interest among immunologists [30]. Nevertheless, the mechanisms of the disease remain obscure. The earliest concept of pathogenesis was that allergic alveolitis was an example of a type 3, complement-fixing, immune complex reaction in the lung [31]. In support of this concept was the frequent finding of precipitating antibodies to the inhaled antigen in the blood of farmers, pigeon fanciers and others with the disease. However, many patients, especially among those exposed to budgerigars, did not show such antibodies, while they were found in a surprising number of exposed but well subjects [32,33]. Moreover, the histopathological features suggested that the aetiology was more complex, since vasculitis was usually absent and granulomas were present. Interest therefore started to centre on cell-mediated reactions and, in particular, on the roles of macrophages and lympho-

cytes [34]. The popularization of the technique of BAL allowed study of the cellular reactions within the acinus, including studies of the functional status of cells so obtained. Even so, the precise immunological or para-immunological mechanisms have still not been clearly defined.

Features that seem to be usual in patients with allergic alveolitis are a response to inhalational challenge with the offending antigen in terms of fever, polymorphonuclear leucocytosis with fall in total blood lymphocyte count, and evidence of impairment of acinar lung function [35]. Bronchial washings in patients with active allergic alveolitis (Fig. 37.5) show an increased proportion of lymphocytes up to about 80% of the total count and averaging about 60% [36,37]. Studies of T-cell subtypes in BAL fluid have shown findings similar to those in peripheral blood, with a relative excess of suppressor CD8 over helper CD4

(a)

(b)

**Fig. 37.5** Bronchoalveolar lavage from (a) patient with allergic alveolitis showing large numbers of lymphocytes together with macrophages and some polymorphonuclear leucocytes and (b) from normal subject showing macrophages.

T lymphocytes [38]. Curiously, exposed but unaffected subjects have also been shown to have raised lymphocyte counts and proportions in their alveolar fluid [39]. However, functional tests of BAL lymphocytes *in vitro* have shown that those from symptomatic subjects with bird fancier's lung increase markedly in blastogenic activity when stimulated with phytohaemagglutinin or pigeon serum compared with the response of cells from exposed but asymptomatic subjects [40]. A soluble protein associated with suppressor T lymphocytes, sCD8, has been shown to augment proliferation of lymphocytes when stimulated with relevant antigen [41], while the proinflammatory cytokines macrophage inhibitory factor and interleukin (IL)-8 (which attract CD8 T lymphocytes and neutrophils respectively) have been demonstrated in high concentrations in BAL fluid from patients with allergic

alveolitis [42]. Other macrophage cytokines identified in various animal models include IL-1 and tumour necrosis factor  $\gamma$  and various growth factors [30], some of which can be released by immune complexes and lead to the formation of granulomas.

In addition to increased numbers of lymphocytes in BAL fluid of exposed subjects, those with disease may also show high counts of mast cells, up to about 5% of the total cell count [43–45]. In different studies, the proportions of these cells have been shown to fall to normal, but the absolute numbers to rise, when exposure ceases [43,44]. Increases in neutrophil leucocytes, averaging 10% of the total cells, may also be observed in the exposed individual, falling when exposure ceases. Indeed, a transient and often severe bronchoalveolar neutrophil leucocytosis has been shown to be an important component of the initial

response to bronchial challenge, appearing within 24 h of exposure and clearing within a week [46]. Finally, plasma cells may be found in BAL fluid from patients with acute allergic alveolitis and are rarely found in any other condition [47,48]. They may therefore be of some diagnostic value.

The evidence suggests that people exposed to these organic antigens may develop a complement-fixing, IgG-mediated reaction detectable by precipitating antibodies in serum. In addition, and despite remaining perfectly well, they may have a lymphocytic alveolitis following release of cytokines from alveolar macrophages challenged by the antigen. In those in whom disease develops, the functional activity of the lymphocytes is altered; it may be that this is responsible for the formation of granulomas, since these cells produce lymphokines that inhibit macrophage migration. Furthermore, the T cell may also produce other lymphokines and leukotrienes that attract mast cells and cause them to release their mediators [49,50]; this would provide an alternative explanation to a type 3 reaction for the oedema, though the absence of eosinophils in the pathology of the disease is a point against an important role for mast cells. Nevertheless, degranulation of mast cells may contribute towards the disease [44,45].

Bronchoalveolar neutrophil leucocytosis seems to be a common response to inhalation of a number of irritant and toxic particles. The histology of so-called mycotoxicosis shows neutrophils and, as mentioned above, many subjects with acute allergic alveolitis have blood and bronchoalveolar neutrophilia early in the course of the disease. There is good evidence that in some subjects activation of the alternative pathway of complement may occur in response to dust inhalation; it may be that this could be important in some of the more acute, precipitin-negative cases [51].

The question remains why some exposed individuals develop neither disease nor immunological response, some develop the response in terms of antibodies and/or lymphocytic alveolitis but no disease, and some develop disease with striking changes in both proportions and functions of alveolar inflammatory cells. Dose of antigen exposure probably plays a part [52], as does the immunomodulatory (in this case, suppressive) effect of cigarette smoke [53]. Genetic factors have not yet been identified and, despite the sacrifice of many rats, mice and rabbits, the question remains unanswered. It is perhaps fortunate that satisfactory management of the condition does not depend on understanding its mechanisms.

## Diagnosis

A physician scanning the literature on allergic alveolitis might get the impression that diagnosis is complicated and requires the use of many sophisticated and, for the

patient, uncomfortable tests. Happily this is not so, as in most cases the diagnosis can be made by taking a competent history and by the use of stethoscope, simple laboratory tests, chest radiograph and lung function testing, supplemented if necessary by a visit to the site of the suspected antigen source. Only occasionally are challenge testing, bronchoscopy with lavage and transbronchial biopsy necessary.

## History

Acute episodes usually bear a clear relationship to the exposure and are recognized by the patient. The more subacute presentation is often regarded as recurrent bronchitis or asthma by the primary care physician and is more difficult to pin down to antigen exposure. All patients with respiratory symptoms suggestive of allergic alveolitis should be asked about exposures at work or home to dusts and moulds, birds and small animals, and volatile chemicals (as well as drugs, see Chapter 55). One potential source of antigen that may be overlooked is feathers in cushions or pillows. This was the proven cause of chronic allergic alveolitis in the first patient with the condition investigated by the author many years ago, and a similar case resulting from exposure to goose feathers in a duvet has been described more recently [54,55]. Attention should be paid to any improvement in symptoms that may occur with the season or on holiday. However, apart from suggesting a possible source of antigen, the history in subacute and chronic allergic alveolitis is often of non-specific respiratory symptoms with little or no diurnal variation.

## Physical examination

The crucial finding is of repetitive inspiratory crackles. If these are persistent, they indicate disease and justify further investigation. They are virtually always present in acute, subacute and chronic disease and their absence should cast doubt on the diagnosis, tipping the scales in favour of sarcoidosis. Other causes of such crackles in the relatively young and middle-aged people who predominantly suffer from allergic alveolitis are nowadays quite uncommon. The finding of finger clubbing is a strong pointer against allergic alveolitis and towards cryptogenic pulmonary fibrosis.

## Blood tests

In someone with appropriate clinical features, the finding of precipitins to the suspected antigen in the serum can normally be taken to clinch the diagnosis. The straightforward gel diffusion test may not be adequate to detect antibody in a number of subjects, and many laboratories now favour a quantitative radioimmunoassay [56]. This

technique is more sensitive but detects antibody in a higher proportion of exposed but unaffected subjects. However, the higher the titre, the greater the likelihood that disease is present, and in the clinical setting sensitivity is invaluable in a test used to complement clinical findings.

### **Radiology and lung function testing**

As stated before, the chest radiograph may be misleadingly normal in subacute disease; indeed the presence of a relatively normal film in a patient with diffuse inspiratory crackles should alert the physician to the possibility of allergic alveolitis as a diagnosis. In acute episodes the film is usually convincingly abnormal, and here the problem is differentiating allergic alveolitis from other causes of diffuse shadowing. To this extent, the radiographic changes are non-specific. The usual abnormality of lung function, a reduced carbon monoxide diffusing capacity, is also non-specific but is a useful indication of parenchymal disease justifying further investigation. The chief value of chest radiography and lung function testing lies in follow-up of the patient after removal from exposure in order to assess response.

### **More complex investigations**

In most patients the cause of the disease is clear from the above investigations, and the physician is able to plan appropriate management monitored by the same tests. Occasionally, however, the cause is not clear and further investigations are necessary. The first essential is to establish the diagnosis and to exclude other causes of interstitial lung disease. This may be done by biopsy or immunological testing. Biopsy requires an adequate specimen and the transbronchial method is rarely satisfactory in this respect; increasingly, surgeons are offering thoracoscopic biopsy, enabling several good-sized specimens to be taken with control of bleeding and air leaks by stapling [57]. It seems likely that this method will displace all others where appropriate surgical expertise is available. However, biopsy does not always enable a certain diagnosis of allergic alveolitis, especially if a granuloma is not included in the sample or in more chronic cases, and never helps establish the cause. It therefore has its main application in patients in whom there is a serious likelihood of some other disease being present. BAL is frequently performed as part of the investigation, although the usually lymphocytic alveolitis (with a ratio of suppressor to helper T cells greater than unity and with plasma cells sometimes present) is no more than a guide to the diagnosis without usually giving specific aetiological information. However, if a likely antigen has been identified it can then be used not only to search for precipitating antibodies in the blood but also to look at specific proliferative responses of bron-

choalveolar lymphocytes to antigen stimulation [58]. It can also be used in challenge testing, where a small dose is administered to the subject by nebulizer and response measured in terms of white cell count, temperature and lung function tests (see later).

If an antigen is suspected but unknown, a visit to likely sources is worth while. Search of a patient's house for fungi, air conditioners or exotic pets may sometimes be revealing, as may a careful look around the workplace. In doing this, the physician should not confine the search to seeking known antigens; any organic material capable of generating particles of respirable size should come under suspicion, including dusts that might contain fungi or animal material, and fumes at work. Particular attention should be paid to stored organic matter that could have become damp and mouldy, to damp places or rotten wood where fungi could sporulate and to ducted or blown air conditioning or heating systems. Furnishings may contain feathers or straw; the author has diagnosed allergic alveolitis in a housewife due to feathers in cushions, as mentioned above, and also in an upholsterer due to contaminated straw in antique furniture. If a source of antigen is detected in a workplace, further study of all those exposed using epidemiological techniques is usually desirable. Ultimate confirmation of the diagnosis may depend on demonstration of a response to either withdrawal from exposure or challenge with the suspected antigen. The simplest procedure, and that most usually practised, is to remove the antigen source or to have the patient change his or her work practice and to follow the response in terms of lung function. A slow but steady improvement would be anticipated, although complete recovery may never occur in more chronic disease. Alternatively, a challenge test may be carried out. The simplest form of this is to expose the subject to antigen in the normal way, for example a farmer is exposed to mouldy hay or a worker exposed to the suspect fumes or dust in the workplace, and appropriate measurements made. Alternatively, the exposure may take place in the laboratory, either to crude antigen or to purified extracts. The latter is appropriate if the subject is exposed to a known antigen but if it is not certain whether or not the disease is present.

Laboratory challenge tests require decisions about dose of exposure. It is always wise to precede them with a skin-prick test, since if immediate hypersensitivity is present a severe bronchial reaction may occur. The dose of antigen may be estimated very roughly from the history, in terms of severity of reaction, and may be adjusted by time, by concentration or both. For example, using budgerigar or pigeon serum it is usual to challenge first with a 1/100 dilution, then (if no reaction occurs) on another day with a 1/20 dilution and finally with a 1/5 dilution of 1 mL neat serum. Similar dilutions can be made of mouldy hay extract and of fungal antigens. Clearly, laboratory

**Fig. 37.6** Rise in temperature and fall in lung diffusing capacity following challenge with budgerigar antigen. Ideally, a smaller dose might have been given to avoid too great a fall in diffusing capacity.

challenge testing is not an exact science and should be approached with caution. The subject should remain in hospital under observation for 36h and corticosteroids should be available to treat severe reactions. The response to challenge tests may not be as clear-cut as one would anticipate. The most obvious response is a feeling of malaise, with fever, aches and exertional dyspnoea (Fig. 37.6). These are associated with a rise in exercise ventilation, temperature, neutrophil count in the blood and respiratory frequency during exercise, together with a fall in circulating lymphocytes and forced vital capacity [35]. Changes in diffusing capacity and the chest radiograph may occur, but only in severe reactions that are best avoided. Criteria for a positive response proposed by Hendrick and colleagues are shown in Table 37.1. If three or more of these tests are positive within 36h of the challenge test, there is a high likelihood that the antigen has been found. A scheme for the investigation of suspected allergic alveolitis is given in Fig. 37.7.

## Management

Acute episodes of allergic alveolitis may require hospitalization and oxygen therapy to help the patient during the reaction; occasionally hypoxaemia may be so severe and the lungs so stiff as to necessitate assisted ventilation. Corticosteroids should be given for all but the mildest attacks, in a dose of 40mg prednisolone daily until lung function and  $PO_2$  have improved to clinically adequate levels. A controlled trial in acute farmer's lung

**Table 37.1** Response to challenge testing [35].

Test	Change	Specificity (%)	Sensitivity (%)
Exercise minute ventilation	>+25%	94	40
Exercise respiratory frequency	>+25%	94	30
Body temperature	>37.2°C	95	78
Neutrophil count	+2.5×10 <sup>9</sup> /L	96	68
Lymphocyte count	>-0.5×10 <sup>9</sup> /L*	97	52
Vital capacity	>-15%	97	48

\*When combined with absolute lymphocyte count of <1.5×10<sup>9</sup>/L.

has shown that an 8-week course of corticosteroids speeded functional recovery but that longer-term lung function did not differ between the active and placebo groups [59].

Further exposure to antigen should if possible be prevented. In the case of exposure to birds, the creatures must be removed if possible. Unfortunately, for financial and social reasons, many pigeon breeders are unwilling to do this; in such cases effective oronasal respirators should be used whenever the loft is entered. Cross-reactivity occurs, so that pigeon breeders may get exacerbations when they visit houses with budgerigars and they should be warned of this possibility. It should be noted that after a bird has been removed from a patient's house it may find a home with a relative whom the patient visits; in the author's experience this has caused recurrent disease, sometimes manifesting as quite severe attacks. Moreover, bird antigen may persist for months in a room after the bird has been removed, despite careful cleaning, and this may explain persisting symptoms in some very sensitive patients [60]. Farmers often require respirators, but should also be given advice about keeping hay dry or changing to making silage (though this may require some education also on avoidance of silo-filler's lung and mycotoxicosis). Colleges of agriculture can usually give appropriate advice, as can the Health and Safety Executive in the UK.

The use of respirators requires some comment [61,62]. These should be well fitting and well maintained. Filters should be changed regularly and should be adequate to exclude respirable-sized particles; in the UK and the USA, they are subject to testing against standards and should not allow penetration of more than 1–2% of a standard aerosol. If a subject is advised to obtain a respirator, an appropriate one should be recommended and the patient instructed in its fitting, use and maintenance. Care should be taken to ensure that one is chosen that provides a good seal without too much discomfort or respiratory resistance. Powered helmet-type respirators, as opposed to

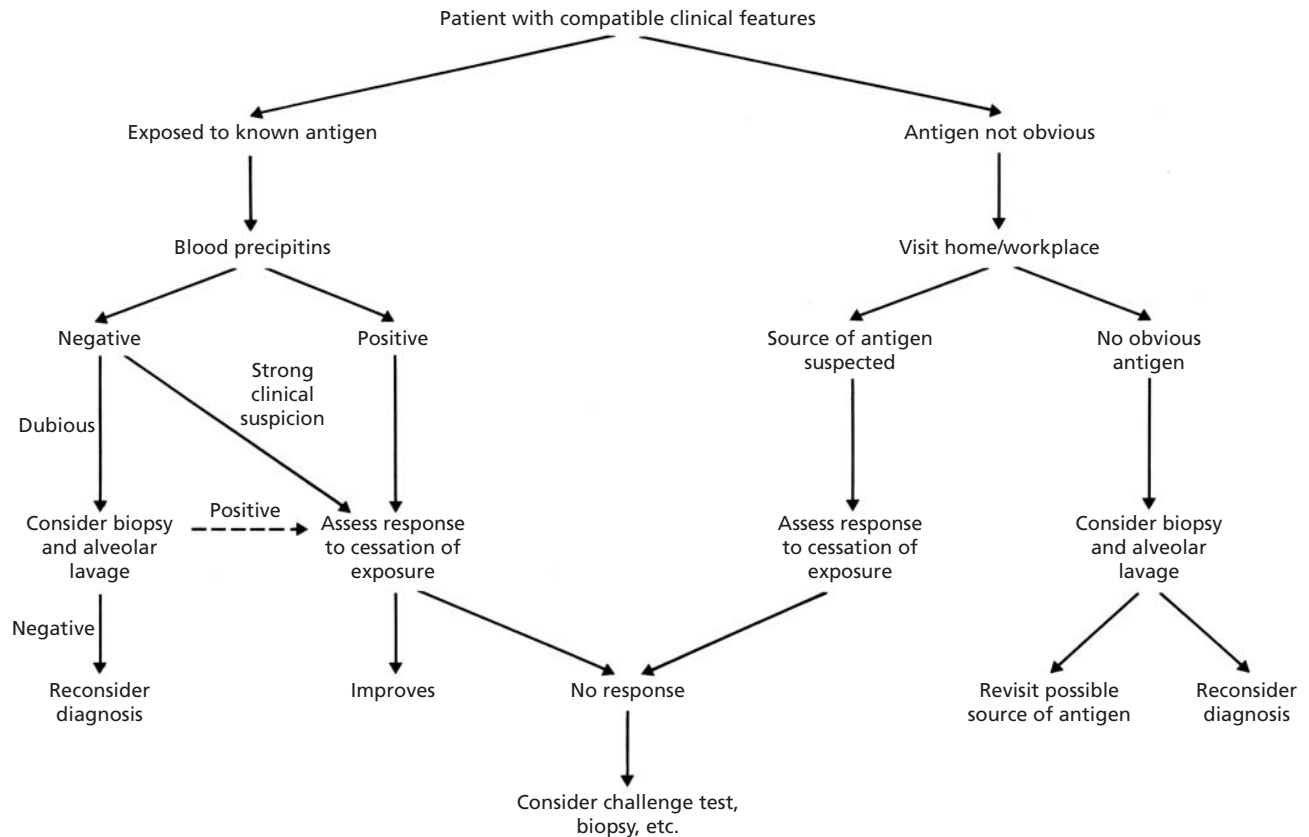

Fig. 37.7 Investigation of suspected allergic alveolitis.

mask types, may be adequate, depending on the efficiency of the filter and the sensitivity of the patient to antigen. Before the subject purchases a respirator, it is wise to test its efficacy in preventing symptoms under normal exposure conditions. Chronic allergic alveolitis should be treated with a prolonged course of corticosteroids, usually for several months, until it is clear that no further functional improvement will occur. The drugs should then be stopped, assuming that further exposure can be prevented. The airways' obstructive component does not respond adequately to corticosteroids, and there is no point in continuing these drugs long term in the hope that it will. However, it should be remembered that asthma sometimes coexists with allergic alveolitis and trials of antiasthma therapy are always justified in such patients.

### Causes of allergic alveolitis

The causes of allergic alveolitis may be separated into three main types: microbial, animal and chemical. In addition there is a small group in which the antigens have not been identified. The main causes are listed in Table 37.2.

### Microbial causes

#### Farmer's lung

Farmer's lung commonly presents in the acute form, although chronic cases may go unrecognized for long periods [9,10,27]. It is usually caused by inhalation of spores of thermophilic actinomycetes, higher bacteria of a filamentous appearance that grow in hay or other organic matter that has been stored in a damp condition. The two most usual organisms in the UK are *Micropolyspora faeni* (now known as *Faenia rectivirgula*) and *Thermoactinomyces vulgaris*, though other organisms including fungi of *Aspergillus* species may sometimes cause the syndrome. The spores are liberated into the air when the dried mouldy hay is fed to cattle, usually in the winter. The condition occurs most commonly in countries where rain is frequent at harvest time and among farmers unaware of the problem. Studies of the epidemiology have shown a prevalence of 3–5% of farmers in agricultural areas of Britain and the USA, most cases occurring in the areas of highest rainfall [20,32,63,64]. Precipitating antibodies in the absence of disease are found in approximately twice as many subjects, and can therefore only be taken as an indication of exposure unless the farmer has appropriate symptoms and signs as well. As with other types

**Table 37.2** Principal causes of allergic alveolitis.

Antigen source	Disease
<b>Microbial</b>	
Thermophilic actinomycetes ( <i>Micropolyspora faeni</i> , <i>Thermoactinomyces vulgaris</i> )	Farmer's lung Bagassosis Mushroom worker's lung
<i>Aspergillus clavatus</i>	Air conditioner lung
<i>Aspergillus fumigatus</i>	Maltworker's lung
<i>Aspergillus versicolor</i>	Allergic aspergillosis
<i>Alternaria</i> spp., <i>Trichoderma</i> <i>koningii</i>	Doghouse disease
<i>Aureobasidium pullulans</i> , <i>Graphium</i> sp.	Wood-pulp worker's lung

Trimellitic anhydride, hexahydrophthalic anhydride	Acid anhydride lung
<b>Uncertain</b>	
Lake water	Sauna lung
Hut thatch	New Guinea lung
Boxwood	Ramin lung

of allergic alveolitis, smokers are less likely to have the disease than non-smokers [64].

It is worth noting that farmers are subject to a number of respiratory disorders as a result of their work [65] (Table 37.3). Farmer's lung, both acute and chronic, may be associated also with asthma due to hay or its contaminants. On the acute side, with negative precipitins, farmer's lung merges into the acute organic dust (mycotoxicosis) syndrome [13]. Farmers may also have asthma and rhinitis due to exposure to fungi in harvesting grains and to mites in stored grains [66,67]. If they keep livestock

**Table 37.3** Respiratory diseases of farmers.

Farmer's lung, farmer's fever	Actinomycetes
Mycotoxicosis	Fungi
Asthma/rhinitis	Fungi, storage mites

Silo-filler's disease	Nitrogen dioxide
Organophosphate poisoning	Insecticides

under conditions of intensive rearing, they may be subject to alveolitis or febrile reactions due to excreta and their contaminants [68], while chemical pneumonitis may occur as a result of exposure to oxides of nitrogen in silos [69]. To make life more difficult for the clinician, they may also present like anyone else with *Mycoplasma pneumonia*, which mimics either farmer's lung or silo-filler's lung [21]. A febrile illness like farmer's lung but without the pulmonary component has been described [70] and farm workers are of course at risk of poisoning by organophosphorus compounds, which can in severe cases lead to neuromuscular paralysis.

The diagnosis of farmer's lung is usually easy; indeed it is often made by the patient. If it is made sufficiently early in the course of the disease, preventive measures should be effective and progression should not occur. However, continued exposure is associated with a high risk of progression [71]. Only in difficult, precipitin-negative cases are further investigations necessary, and these should usually be preceded by a visit to the farm to make sure there is no other source of antigen that has been overlooked in the history.

Management is as discussed above. Since farmers are rarely able to retire or change jobs, it is important that they be educated in preventive measures. Equally, they should not simply hand over the dusty job to their wife or other assistant, as that is likely to produce a second case. Transfer from hay to silage, proper drying of damp hay and use of a respirator when exposure cannot be prevented [72] are the principles of management. In the UK, employed farmers with the disease (not self-employed, who have to make their own insurance arrangements) are eligible for industrial injuries benefit under the national social security scheme.

### Mushroom worker's lung

Mushrooms are grown commercially on compost, often made of straw and horse droppings that is allowed to ferment, which is then heated in moist air to just below 60°C. While these conditions suit the mushroom mycelia with which it is seeded, they are also ideal for the growth of thermophilic actinomycetes. Workers may be exposed to spores when compost and mycelia are mechanically mixed or when the sheds are being cleaned. The manifes-

tations of the disease are clinically indistinguishable from those of farmer's lung [73–76].

### Bagassosis

Bagasse is the residue after sugar is extracted from cane. It is a fibrous material used in the manufacture of paper, boards and building materials. Typically it becomes contaminated with thermophilic actinomycetes when lying in the hot and humid conditions of Louisiana, the West Indies and other tropical and subtropical areas where sugar cane is processed. Although the disease commonly affects workers handling the bagasse in these countries, it may also occur wherever mouldy material is imported [77–79]. Indeed, it was first described in London, in workers handling bagasse imported from Louisiana [3]. Again, the disease is a variant of farmer's lung.

### Air conditioner and humidifier lung

(see also Chapter 54)

Many workers exposed to 'conditioned' air (air in which the humidity and temperature have been controlled to produce comfortable conditions) suffer mild general malaise known as humidifier fever [80,81], particularly on the first day of the week; however, some develop a true allergic alveolitis [82–86]. Various organisms have from time to time been incriminated, since conditions differ in different conditioning and humidifying systems, leading to preferential growth of different organisms. In some episodes, thermophilic actinomycetes have been thought to be responsible, in some *Aspergillus* spp., in others *Penicillium* spp. and thermotolerant bacteria resembling *Bacillus cereus* [87], while in some the cause has not been identified [88]. In general, humidifier fever, in which the predominant antigen source is *Naegleria gruberi* or other amoebae, is not associated with evidence of interstitial lung disease, although at least one patient with typical radiological and physiological changes has been described [86].

This spectrum of responses, from classical allergic alveolitis to humidifier fever, results from exposure to droplets from humidifying systems in which the water is sprayed into a moving stream of air. The drops that fall and the larger droplets removed by a baffle are collected in a sump and then recirculated and sprayed again. The sump and the baffle plates form a culture medium for microorganisms, and a food chain develops depending on temperature and nutrients. In theory this can be prevented by spraying steam or fresh (rather than recirculated) water, although these options are often expensive. Alternatively, the incoming and outgoing air can be filtered and/or subjected to ultraviolet light and biocides can be added to the water. Measures taken depend on the system and on economic factors, but must include regular cleaning of the

whole system. If the water is heated, the temperature should also be raised above 60°C in order to discourage the growth of *Legionella* spp. (see Chapter 13).

An identical range of syndromes may occur from exposure to contaminated aerosol from home ultrasonic nebulizers. An outbreak in Japan has been associated with an aerosol containing *Cephalosporium* and *Candida* spp. [89], while one in the USA has been caused by *Klebsiella oxytoca* [90].

### Maltworker's lung

Malt is used as a source of carbohydrate for fermentation in the manufacture of whisky. It is barley that has been dried, stored and then rehydrated and allowed to germinate in conditions of controlled temperature and humidity. The process may take place on the floor of a large room, the maltings, where the material is turned regularly to allow carbon dioxide to escape. Alternatively, it can be carried out in rotating drums. In the former situation, the malt may become contaminated with *Aspergillus clavatus* and workers may inhale spores of this organism [91–93]. The condition has been shown to cause a farmer's lung-like illness in up to 5% of those workers who turn the malt.

### Woodworker's lung

Allergic alveolitis has been described in several different groups of woodworkers. Indeed, maple bark stripper's lung was described in the same year as farmer's lung [2]. These workers were exposed to the spores of *Cryptostroma corticale*, a fungus that grows under the bark and which is pathogenic to the tree [94]. The spores are liberated when the bark is mechanically removed in lumber mills [95–97]. The incidence of the disease may be controlled by hygiene measures, such as extract ventilation and spraying of the dusty process. Similar illnesses have been described in workers in paper mills due to inhalation of spores of *Alternaria* spp. [98], in sawyers of redwood (sequoiosis) due to *Graphium* spp. or *Aureobasidium pullulans* [99], in other sawmill workers due to *Trichoderma koningii* [100], and in workers making cork (suberosis) due to *Penicillium frequentans* [101,102]. One subject working with ramin dust has also been described as developing allergic alveolitis, probably due to the wood dust itself rather than to a fungus [103].

### Aspergillosis

Allergic bronchopulmonary aspergillosis is discussed in detail in Chapter 34 and other diseases related to *Aspergillus* spp. in Chapter 21. Since *Aspergillus* spp. grow on dead organic matter, they can be found in mouldy hay and in compost heaps and may therefore cause episodes of

allergic alveolitis in farmers and market gardeners. A severe episode, requiring assisted ventilation, occurred in a patient as a result of changing straw contaminated with *A. versicolor* in her dog's kennel [104].

### Cheeseworker's disease

This relatively mild and chronic form of allergic alveolitis was described originally in Swiss cheese washers, whose job was to wash off mould that had grown on the surface of some cheeses aged in damp cellars. On the basis of blood serology the condition was thought to be due to sensitization to *Penicillium casei* [105–107]. Although the condition was thought unlikely to occur in industries in which cheese was aged by wrapping in plastic, it has subsequently been described in a worker in the USA who was engaged in crumbling blue cheese in the production of salad dressing; in this case the organism was the *P. roqueforti* used to give the cheese its distinctive flavour [108].

### Japanese summer pneumonitis and other domestic causes

A distinctive type of allergic alveolitis, in which the symptoms occur in the patient's home during the summer months, has been described in Japan where it is the commonest form of allergic alveolitis [18,109,110]. This is caused by *Trichosporon cutaneum* in the houses, particularly in bird droppings, which enhance the organism's growth. In one case, the mould was growing in bed-clothes. As with other forms of allergic alveolitis, the condition is less common in cigarette smokers [53]. Immunological studies in these cases have shown antibodies cross-reacting with *Cryptococcus neoformans*, a related yeast, and a particular rise in IgA antibodies to *T. cutaneum* in both blood and BAL fluid [111,112]. The antigen has been characterized as a polysaccharide with glucuronic acid residues on side-chains forming the epitope [113].

It would not be surprising if other episodes of alveolitis occur as a result of exposure to fungi in houses. Several such have been described, including reactions to the dry rot fungus, *Merulius lacrimans*, and to *Penicillium* spp. growing in wet rot [114,115]. *Bacillus subtilis* growing in rotten wood has also been shown to cause the disease in a family [116].

### Other causes

An entomologist who developed allergic alveolitis in response to workplace exposure to antigen of *Penicillium* spp. and from humidifiers has been described [117]. Some of the workers exposed to *B. subtilis* in the manufacture of biological washing powders may have developed alveoli-

tis as well as asthma; certainly precipitating antibodies were found in their blood [118,119]. Workers splitting red peppers, or paprika, used to be exposed to heavy doses of spores of *Mucor* spp. and several cases of what was probably alveolitis were described among them [120]. An alveolitis associated with fever was also described in children using inhalation of puff-ball (*Lycoperdon*) spores to stop nose bleeds [121]. This last case report made the interesting suggestion that the disease could be prevented if the puff-balls were picked when young, sautéed in butter and garlic, and eaten rather than inhaled!

### Animal causes

#### Bird fancier's lung

This condition was first described in 1960 in people plucking ducks and those exposed to budgerigars, and in 1965 in people breeding pigeons [4,5,122,123]. Chicken and turkey farmers may occasionally develop the disease and it has also been described in a bird ringer [124–126]. The presentation in people who keep the birds in their houses is often insidious and may be mistaken for neurosis, recurrent chest infections or asthma. In children, loss of weight or failure to thrive may be the presenting feature. Acute attacks occur most commonly in pigeon breeders, following visits to the loft. Re-exposure to a bird after exposure has ceased may also provoke a severe attack, and cross-reactivity may mean that a pigeon fancier suffers an attack on visiting a house where a budgerigar is kept. Otherwise the symptoms do not differ from those associated with other types of allergic alveolitis, shortness of breath, cough, malaise, wheeze and fever being the important ones [127]. The radiograph is often within normal limits in the more chronic cases, although crackles are usually audible at the bases. Lung function commonly shows a restrictive pattern with reduced diffusing capacity, but an obstructive syndrome can occur [128–130].

The frequency with which the condition occurs depends on the prevalence of bird exposure and the extent of that exposure; this is presumably why budgerigars (kept in some 12% of British homes) and pigeons are the most common sensitizers, since exposure to budgerigar antigen is unavoidable if the creature lives in the house while pigeon fanciers have intimate contact with their animals. Among pigeon fanciers, alveolitis has been estimated to occur in about 10–20% of those regularly visiting the lofts [131]. While precipitating antibodies often occur in exposed people without disease [132], the intensity of IgG response measured by radioimmunoassay is a good guide to the likelihood of disease being present [133].

The sensitized patient has precipitating antibody to bird serum protein and droppings. At least in pigeons, IgA seems to be the most important antigen; it was originally thought that this would be inhaled in dried bird faeces,

although it now seems likely that bloom from feathers is the principal source [134,135]. Bloom consists of <1.0- $\mu\text{m}$  spherical particles of keratin coated with IgA that cover the feathers and give them their glossy appearance (Fig. 37.8). It relates to the appearance of the bird and its ability to fly efficiently, and is therefore abundant on the wings of ornamental and sporting birds.

Two practical problems may occur in the diagnosis of bird fancier's lung. Firstly, false-positive titres of viral complement-fixing antibodies may be found due to either polyclonal stimulation of antibody formation or cross-reactions with proteins in the egg on which the virus was

grown, leading to confusion with viral pneumonia [15,136]. Secondly, patients with coeliac disease may have precipitins in their serum to bird antigen, probably derived from egg protein in their food [137]. However, it appears that there is an association between bird fancier's lung and coeliac disease as well, and therefore the coincidence of coeliac disease with interstitial lung disease is one situation where inhalation challenge may be invaluable [138-140].

Management of bird fancier's lung is by preventing further exposure. Usually this may be achieved by removal of the birds; if this involves serious financial or

(a)

(b)

emotional hardship, use of effective respirators may be a compromise [62]. As noted above, residual antigen in rooms vacated by birds may persist for months despite cleaning [60], and patients should be advised to keep out of the room in which the bird has been kept if possible. All patients should be warned of the dangers of irreversible pulmonary fibrosis if they are contemplating continued exposure. Corticosteroids are effective treatment for acute episodes and bring about partial improvement in most chronic cases if exposure is stopped.

### Other animal causes

Apart from those caused by birds, episodes of allergic alveolitis due to exposure to animal protein have been described rarely. Small laboratory mammals frequently provoke asthma as a consequence of sensitization to urinary protein, and an occasional case of allergic alveolitis has been described in people exposed to rats and gerbils [141,142]. A granulomatous interstitial pneumonitis (probably of foreign body rather than immunological aetiology) has been described in a person handling animal furs [143], and a patient exposed to the wheat weevil, *Sitophilus granarius*, developed alveolitis as well as the more typical asthmatic reaction [144]. Workers making fishmeal as animal food may become sensitized and develop allergic alveolitis [145].

Alveolitis has been described in the production and use of two therapeutic substances. Pituitary snuff-taker's lung occurred in patients with diabetes insipidus taking extracts of porcine or bovine pituitary by nasal insufflation [146,147]. The particles of this were mostly below 50 µm, and some were small enough to reach alveoli and cause a chronic allergic alveolitis. Sensitization was usually to contaminating ox or pig protein but in one case was to the hormone itself [148]. Since synthetic vasopressin has been introduced the problem has not recurred. More recently, workers producing pancreatic extract have been described as developing alveolitis [149]. This substance has been known to cause asthma and is under suspicion of provoking emphysema in exposed workers, although one report has also documented a late alveolitic reaction to challenge testing and radiological evidence of interstitial disease in a few people employed in its production [149].

### Chemical causes

In view of the relatively large numbers of subjects who

develop asthma as a consequence of exposure to volatile reactive chemicals, it is surprising that so few have been described as developing alveolitis. This is particularly remarkable because the atopic state is not an important determinant of occupational asthma due to low molecular weight chemicals and their particle size is such that deposition is not likely to be preferentially in airways. Nevertheless, few chemical causes of alveolitis have been described and few patients have suffered these effects. Several volatile isocyanates have caused alveolitis, combined in some subjects with asthma [6,8,150–153]. A haemorrhagic pneumonitis has been associated with exposure to trimellitic anhydride, and allergic alveolitis and haemorrhagic rhinitis associated with IgG antibodies with exposure to hexahydrophthallic anhydride, acid anhydrides used in epoxy resin systems [154,155]. Typical allergic alveolitis and asthma have occurred in a laboratory technician using Pauli's reagent (sodium diazobenzene sulphonate) in chromatography [7]. Cobalt, to which workers in the hard-metal industry may be exposed because of its presence in coolant sprays in grinding and also in small amounts in the tungsten carbide metal itself, may cause both asthma and alveolitis, the latter sometimes leading to pulmonary fibrosis [156,157]. Pyrethrum, an extract of autumn crocus used in insecticides, has caused alveolitis in one subject [158], and exposure to Bordeaux mixture (copper sulphate neutralized with lime) in spraying vines has also caused a similar reaction [159].

### Possible causes and some non-causes

Chronic lung disease in Papua New Guinea, though probably usually due to smoke inhalation, may occasionally be an allergic alveolitis due to inhalation of fungi or other contaminants in thatch [160]. Lake water constituents may be the cause of alveolitis described in Finland in people using saunas [161]. Three possible episodes of alveolitis have now been discounted: smallpox worker's lung turned out to have been a pneumonia modified by vaccination [162]; coffee worker's lung was a pulmonary fibrosis in association with rheumatoid disease [163]; and blackfat tobacco smoker's lung turned out to be a lipid pneumonia [164]. As mentioned above, furrier's lung seems likely to have been a foreign body granulomatous, rather than allergic, reaction.

# PULMONARY EOSINOPHILIAS

A. GORDON LEITCH

## Definition

The term 'pulmonary eosinophilia' was originally applied as a general one to a group of diseases in which lung shadows were observed radiologically and were accompanied by a blood eosinophilia. Resolving pneumonia, sarcoidosis, hydatid disease and Hodgkin's disease were excluded [1]. Some workers have used the term 'pulmonary infiltration with eosinophilia' (PIE syndrome) [2] and because eosinophilic infiltration of the lung can exist in the absence of blood eosinophilia, it has been suggested that the term 'the eosinophilic pneumonias' might be even more appropriate [3]. The terms are interchangeable but pulmonary eosinophilia is retained in this chapter for historical reasons.

Opinions vary on the level of blood eosinophil count that constitutes eosinophilia. In one study 95% of healthy non-allergic subjects had eosinophil counts of less than  $0.27 \times 10^9/L$ , whereas counts of greater than  $0.35 \times 10^9/L$  were usually seen in patients with active asthma [4]. Total eosinophil counts of greater than  $0.5 \times 10^9/L$  (and often much higher) are usually seen in patients with pulmonary eosinophilia.

## The eosinophil

The eosinophil polymorphonuclear leucocyte is 12–15  $\mu m$  in diameter, containing a bilobed nucleus, rich endoplasmic reticulum, an active Golgi complex and two types of eosinophilic granules (Fig. 38.1). The larger granules, of which there are about 200 in each cell, are  $1 \times 0.6 \mu m$  in size and comprise an electron-dense crystalloid matrix in which are found a number of enzymes, including a unique peroxidase [5],  $\beta$ -glucuronidase, acid phosphatase and histaminase [6–8]; 25–50% of the mass of the granules consists of the major basic protein (MBP), a 13.8-kDa protein [7,9]. In addition the granules contain eosinophil cationic protein (ECP) (18–21 kDa) [10] and eosinophil protein X (eosinophil-derived neurotoxin) (18 kDa) [11]. The smaller granules, which are more prominent in mature

eosinophils, measure  $0.2 \times 0.2 \mu m$  and are rich in arylsulphatase B and acid phosphatase. The cell membrane contains lysolecithinase, an enzyme that spontaneously forms Charcot–Leyden crystals in tissues and fluids [12] (Fig. 38.2).

Eosinophils are produced in the bone marrow, circulate for 4–10 h and then localize in the tissues, being most prominent in the submucosal sites of the respiratory, gastrointestinal and genitourinary tracts [13]. Their behaviour is influenced by chemotactic factors, chemokinetic factors and deactivation factors. Chemotactic factors cause migration towards a cell-sensed concentration gradient, while chemokinetic factors enhance random motility. Deactivation factors induce unresponsiveness to subsequent chemotactic stimuli, a property that localizes and immobilizes eosinophils in the tissues. Both complement-derived products C3a, C5a and C567 (which may be generated by the classical or alternative pathways [14]) and the mast-cell derived products ECF-A and ECF-A oligopeptide [15] demonstrate the combination of chemotactic and deactivation activities. Chemotactic activity is also shown by lipoxygenase pathway products, such as several of the monohydroxyeicosatetraenoic acids and leukotriene  $B_4$ , which may be generated by several cell types [16]. Eosinophils may therefore be attracted to tissues by many mechanisms, including mast cell activation, complement activation, lymphocyte-derived products and generation of arachidonic products via the lipoxygenase pathway by a variety of cells.

Blood eosinophil counts are depressed by glucocorticosteroids, which also inhibit eosinophil chemotaxis and facilitate eosinophil margination and tissue destruction [17]. Propranolol induces a modest peripheral blood eosinophilia in many patients, suggesting direct  $\beta$ -adrenergic control of eosinophil levels [18].

## Function

The eosinophil is equipped to modulate mast cell-dependent reactions by virtue of the enzymes that it

**Fig. 38.1** Electron micrograph of an eosinophil showing bilobed nucleus, endoplasmic reticulum and prominent intracytoplasmic granules.

**Fig. 38.2** Mucous plug from asthmatic airway showing eosinophils and Charcot-Leyden crystals (haematoxylin & eosin  $\times 335$ ).

produces [19]; histaminase degrades histamine, phospholipase D degrades platelet-activating factor and, in addition, the eosinophil can ingest mast cell granules and IgE-antigen complexes. An eosinophil-derived inhibitor of histamine release, which is probably prostaglandin  $E_2$ , also exists [20]. The marked eosinophilia found in many parasitic conditions suggests a role for the eosinophil in the destruction of parasites [21]. This has been shown to be the case in schistosomiasis, in which eosinophils inflict IgG antibody-dependent damage on the schistosomula [22]. Complement also enhances this process and mast

cells enhance both complement and IgG-dependent eosinophil-mediated schistosomal killing *in vitro* [23]. The eosinophil may function similarly in other parasitic diseases.

Not all the activities of the eosinophil are beneficial. Prolonged hypereosinophilia may be associated with tissue damage and a possible mechanism for this adverse effect has now been identified. Low concentrations of eosinophil MBP have been shown to damage a wide variety of mammalian cells and organs [24]. Concentrations of MBP comparable to those found in the sputum of patients with

asthma have been shown to be ciliostatic and to damage tracheal mucosal cells [25]. Furthermore, using immunofluorescent techniques, MBP has been localized to areas of mucosal damage in the bronchi of patients with asthma [26]. It seems possible that deposition of MBP in the interstitium or vascular tree could cause pulmonary parenchymal or vascular damage in a similar fashion. Other constituents of the eosinophil that could exert a pathogenic effect include superoxide, lysosomal hydrolase, ECP, eosinophil protein X and the inflammatory products of arachidonic acid [27,28].

While knowledge of the factors regulating eosinophil behaviour and function continues to grow, it would be wrong to conclude that more than a start has been made in uncovering the mechanisms that underly the several varieties of pulmonary eosinophilia.

### Classification

In the fourth edition of this book, the pulmonary eosinophilic disorders were classified into seven categories largely on the basis of clinical manifestations. Since then, acute eosinophilic pneumonia has been described [29,30] and the present classification of pulmonary eosinophilias is as shown in Table 38.1 [31].

#### Loeffler's syndrome or simple pulmonary eosinophilia

##### Definition

Originally described by Loeffler in 1932 [32], this syndrome is characterized by transient radiographic shadows and by blood eosinophilia that is usually relatively slight, although high counts have been recorded. The illness usually lasts less than 2 weeks and always less than 1 month and is related to the passage of parasitic larvae, most commonly *Ascaris lumbricoides*, through the lung.

##### Aetiology

The life cycle of *A. lumbricoides* in humans begins with

the ingestion of eggs and subsequent development of larvae in the intestine. Some 10–14 days after ingestion the larvae migrate to the liver and the lung, thence to the alveoli and up the bronchial tree to be swallowed into the intestine where they develop into the mature roundworm.

Koino, a Japanese investigator, swallowed 2000 ripe *Ascaris* eggs and 6 days later developed pneumonia with dyspnoea, cyanosis, eosinophilia and pyrexia that lasted for 7 days. The sputum was profuse from day 11 to day 16 and contained *Ascaris* larvae, of which 202 were counted. By 50 days after infection, 667 *Ascaris* worms were voided in the faeces [33].

The passage of larvae through the lung is associated with an allergic reaction that was well studied in four Canadian students who developed pulmonary eosinophilia 10–14 days after eating a meal maliciously seasoned with *A. suum* ova [34]. Asthma occurred in all four students and urticaria was also a feature of the illness. Studies of immunoglobulin and eosinophil levels in the course of the illness showed that peak humoral antibody levels of IgM and IgE occurred before peak eosinophil levels, which were found in the recovery phase of the illness. The authors concluded from their observations that the high IgE levels were responsible, via a type I hypersensitivity reaction, for the asthma and urticaria and that the pulmonary infiltrates were due to a type III reaction following deposition of IgM–antigen complexes in the lung, perhaps facilitated by the changes in vasopermeability occasioned by release of mast cell mediators. It is of interest that high levels of IgE have been demonstrated in children infected with *A. lumbricoides* [35].

Other parasites implicated in this form of pulmonary eosinophilia include *Paragonimus westermani* [36] and *Ancylostoma braziliense* (see Chapter 22).

##### Pathology

Histopathological sections of lung from a patient dying from Loeffler's syndrome showed that the bronchi and bronchioles were dilated and filled with a neutrophil and eosinophil polymorphonuclear infiltrated exudate [37]. Charcot–Leyden crystals were seen in some areas. In some of the bronchioles one or more portions of nematode larvae were demonstrated. The pulmonary interstitium was also infiltrated with eosinophils and areas of atelectasis were seen.

##### Clinical features

Over 23% of Loeffler's original cases were detected during routine radiography and were asymptomatic. Symptoms when present are usually mild and may include cough, malaise, anorexia, rhinitis, night sweats, slight fever and

occasionally wheezing and dyspnoea [33,34]. Urticaria can occur. Sputum when present may contain eosinophils and, exceptionally, larvae. High fever may occur. Frequently there are no abnormal physical signs in the chest, although impairment of percussion note, a few crepitations or wheezes may be heard. Symptoms and physical signs usually disappear in a few days and almost always within a fortnight.

**Radiology**

The chest radiograph almost invariably shows bilateral involvement, with considerable variation in the extent and location of the pulmonary infiltrates [38]. These are usually scattered soft densities, a few centimetres in size, that tend to be discrete, without any clear-cut segmental distribution and often concentrated in the perihilar regions. In severe cases the densities may coalesce to create more extensive areas of consolidation. The opacities usually disappear within 6–12 days and almost always within a month.

**Investigations and diagnosis**

The white count is usually normal or high normal with a relatively low eosinophilia. Higher counts, with a total eosinophil count of greater than  $5 \times 10^9/L$  or even as high as  $16.5 \times 10^9/L$ , have been recorded. IgE and IgM levels are elevated in the acute phase of the illness but this is little aid to diagnosis [34].

Sputum should be examined for eosinophils and larvae and stools should be examined for parasites. Since the larvae of *Ascaris* only become adult some 6–8 weeks after infestation, eggs are unlikely to be found in the stools before this time. Stools should therefore be re-examined some 2–3 months after the onset of symptoms.

The main diagnostic problem arises from the radiographic abnormality, which needs to be differentiated from pneumonia, tuberculosis and pulmonary infarction. The transient nature of the shadows excludes tuberculosis; microbiology should help to exclude pneumonia; and pulmonary infarction, although it may cause similar pulmonary shadows, is not associated with eosinophilia unless there is a contemporaneous chronic parasitic infection.

**Treatment**

As the condition is usually mild, no specific therapy for the pulmonary eosinophilia is required. With severe manifestations oral corticosteroid therapy is extremely effective [34]. The *Ascaris* infestation may be treated with piperazine citrate 4 g in a single oral dose given after the larvae have developed into adult worms.

**Asthmatic pulmonary eosinophilia or allergic bronchopulmonary aspergillosis**

**Definition**

Asthmatic pulmonary eosinophilia is characterized by asthmatic symptoms, recurrent shadows on the chest radiograph and blood eosinophilia. The expectoration of inspissated mucus in the form of pellets or bronchial casts is relatively common.

**Aetiology**

This is by far the most common cause of pulmonary eosinophilia and it is seen worldwide. The paucity of cases in North America [39] has been attributed more to failure of recognition than to a true difference in prevalence [40]. The disease may be seen at any age, more commonly in women than men. Most cases are associated with type I hypersensitivity to *Aspergillus fumigatus*, hence the name [41–46]. Of 143 cases of pulmonary eosinophilia reported by McCarthy and Pepys [41], 111 had allergic bronchopulmonary aspergillosis; in a more recent series, 33 of 65 patients with pulmonary eosinophilia met the criteria for this condition [46]. The condition is now well recognized as a serious complication of cystic fibrosis [47,48]. The suggested criteria for a diagnosis of allergic bronchopulmonary aspergillosis are shown in Table 38.2. Other cases may be due to hypersensitivity to *Candida* antigens and individual cases due to hypersensitivity to *Pseudomonas aeruginosa*, *Aspergillus terreus*, *Helminthosporium* and *Curvularia lunata* have been reported [49–53].

The presence of high serum IgE levels in such patients, with marked elevations of IgE during acute episodes of pulmonary eosinophilia, suggests an important contribution from a type I hypersensitivity reaction and the acute rises may represent a response to an increased burden of *Aspergillus* antigen. The occurrence of late skin reactions to *Aspergillus* in many patients has also suggested that type III hypersensitivity mechanisms may be involved. However, it must be confessed that a complete understanding of the immunological mechanisms involved, which are surely more complex than those suggested above, is not yet available. A full account of the

manifestations, diagnosis and treatment of allergic bronchopulmonary aspergillosis is given in Chapter 34.

### **Drugs and pulmonary eosinophilia** (see Chapter 55)

A large number of drugs have been associated with pulmonary eosinophilic episodes (Table 38.3). The pulmonary shadowing usually develops within several days of starting therapy with the drug and resolves within 1 week of stopping the drug, although occasionally episodes may persist for longer periods of time. Recurrence is only seen following rechallenge with the drug. The clinical and radiological features are similar to those of Loeffler's syndrome in the majority, although some cases more closely resemble the severe and prolonged

illness of chronic eosinophilic pneumonia. Some reactions are self-limiting but therapy with corticosteroids is often employed to hasten resolution.

### **Tropical pulmonary eosinophilia**

Weingarten [99] first described the condition of spasmodic bronchitis associated with leucocytosis, marked eosinophilia and a dramatic response to organic arsenicals in India.

### **Aetiology**

The condition has been reported in India, Sri Lanka, Burma, Malaysia, Indonesia, tropical Africa, South America and the southern Pacific [100,101] and may give rise to diagnostic difficulties when seen in immigrants in non-endemic countries [102]. There is little doubt that it represents a hypersensitivity reaction to filarial infestation because:

- 1 microfilariae have been demonstrated in the lung, liver and lymph nodes of typical cases [103];
- 2 high antifilarial antibody titres are found in patients and the titre diminishes after cure [104–106];
- 3 histamine release from basophils challenged with filarial antigen is much higher in patients with pulmonary eosinophilia than in patients with other manifestations of filarial infection [107];
- 4 the condition responds dramatically to antifilarial treatment.

### **Pathological features**

In the early weeks of the disease, histiocyte infiltrates in alveolar spaces give way to eosinophilic bronchopneumonia and eosinophilic abscesses [106,108]. After several months, eosinophils, histiocytes and lymphocytes often organize into nodular patterns, progressively evolving to predominantly histiocytic granulomatous responses marked by increasing fibrosis.

### **Clinical features**

Males comprise 80% of patients. The onset is often insidious with cough, sputum, wheeze, dyspnoea and chest pain [100,106,109]. Fever, weight loss and fatigue are common. These symptoms may continue for weeks or months with remissions and recurrences. Auscultation may reveal rhonchi and/or crepitations.

### **Radiographic abnormalities**

The chest film may be normal, although the typical appearance is of bilateral indefinite mottling uniformly distributed in both lung fields and involving the middle

and lower zones [100,106]. Increased bronchovascular markings may be noted and occasionally mottled shadows become confluent to produce a pneumonic appearance [110]. Cavitation and pleural effusion have also been recorded [111,112].

### Other investigations

There is nearly always an absolute eosinophil count of greater than  $3 \times 10^9/L$ , the usual range being  $5\text{--}60 \times 10^9/L$  [109]. The filarial complement test is positive. The sputum may contain predominantly eosinophils as does bronchoalveolar lavage fluid [113]. A marked increase in IgE concentration occurs, the IgE concentration appearing to be related to the degree of eosinophilia [105,114]. IgE levels are threefold higher in relapsing disease than in the primary disease [114].

Pulmonary function tests have shown an obstructive pattern in the early stages of the disease, progressing to a predominantly restrictive pattern with a decrease in DLCO in untreated long-standing cases [115–117].

### Treatment

Diethylcarbamazine in a dose of 6–8 mg/kg daily should be given orally in three divided doses for 10–14 days or for as long as 4 weeks [100]. Relief of symptoms occurs within a few days, and improvement of pulmonary function tests towards normal is detected in those who are treated early [100,115,116]. Clinical, haematological, radiological and physiological concomitants of the disease may still persist but continue to improve after the completion of 1 month of treatment with diethylcarbamazine [118]. Prolonged delay in treatment may result in irreversible pulmonary fibrosis.

### Chronic eosinophilic pneumonia or cryptogenic pulmonary eosinophilia

This category of pulmonary eosinophilia is characterized by more severe clinical manifestations and, in the absence of treatment, persistence of radiographic abnormalities.

### Aetiology

The aetiology is unknown. Some drugs, notably sulphonamides [119], nitrofurantoin [82] and chlorpropamide [59], have been implicated. In three patients the illness was associated with desensitization for allergic rhinitis [120]. In one case an associated immune complex vasculitis of skin was detected [121]; in others the pathological findings of microgranulomas and vasculitis with many degranulated eosinophils [122] has led to the suggestion that a cell-mediated reaction with release of lymphokines, which summon and activate eosinophils,

results in cellular damage largely mediated by the components of the eosinophil granules. The disease has been seen in association with an exacerbation of long-standing rheumatoid arthritis [123] and with coccidioidal infections [124].

### Pathology

The histological findings are of interstitial and alveolar infiltration with eosinophils and histiocytes [125–127] (Fig. 38.3). The histiocytes contain eosinophil proteins and Charcot–Leyden crystals [128], and ECP is strikingly increased in bronchoalveolar lavage fluid [129]. Eosinophilic abscesses and multinucleated giant cells may be seen; mast cells, many partly degranulated, may be present. In some biopsy specimens, bronchiolitis obliterans, microgranuloma formation and vasculitis have been observed, indicating that the tissue response is not restricted to the alveoli [120–122]. Progression to lung fibrosis has been reported [130].

### Clinical features

The syndrome can occur at any age, although most patients are middle-aged women (female/male ratio, 2:1). Onset in pregnancy has been reported [131] and, although heredity is not considered a factor, the disease has been reported in identical twins [132]. The onset is usually insidious, with an average symptom duration of 7.7 months before diagnosis [133]. Patients may be moderately to severely ill, with cough and mucoid sputum, dyspnoea, malaise, weight loss, night sweats and high fever. Haemoptysis may be present and the clinical picture may mimic that of tuberculosis [125–127,133–136]. If asthma is present it is frequently of recent onset [120]. In the absence of treatment these symptoms may have persisted for weeks or months. Spontaneous remissions and recurrences have been recorded [120,137].

### Radiographic abnormalities

Radiographs typically show dense opacities, with ill-defined margins and without lobar or segmental distribution, arranged peripherally apposed to the pleura [1,120,125,126,133,137]. The opacities are usually axillary or apical but may be basal and mimic loculated pleural effusions. Opacities may disappear and recur in the same or different situations. Peculiar oblique or vertical lines without reference to the hilum or anatomical divisions may appear during resolution of the pneumonia. Gaensler and Carrington [120] described the changes as resembling the photographic negative of pulmonary oedema (Fig. 38.4), although this appearance may also occur in other conditions such as sarcoidosis [138] and bronchiolitis obliterans with organizing pneumonia [139]. Unilateral

**Fig. 38.3** Lung biopsy of patient with eosinophilic pneumonia: (a) intra-alveolar and interstitial infiltration with inflammatory cells (haematoxylin & eosin  $\times 25$ ); (b) bilobed eosinophils with granular cytoplasm, together with some histiocytes and lymphoid cells (haematoxylin & eosin  $\times 170$ ).

chest radiographic abnormalities have also been seen [135].

CT (Fig. 38.5) may show peripheral airspace disease, not always apparent on the chest radiograph [133,140]. Inapparent mediastinal adenopathy may also be detected by CT [140,141].

### Other investigations

In as many as one-third of cases, peripheral blood eosinophilia may not occur [120]. The white blood cell count may be increased and eosinophilia of over  $2.5 \times 10^9/L$  has been recorded [133]. Anaemia is not uncommon [137] and an erythrocyte sedimentation rate (ESR) as high as 100 mm in the first hour is a frequent finding [126,137,142]. Eosinophils may be seen in the sputum [126]. Bronchoalveolar lavage in one patient showed 42%

eosinophils and 48% macrophages prior to therapy, with a normal cell differential count 13 weeks after steroid therapy was instituted [143]. Dynamic lung volumes usually indicate a restrictive pattern and  $DLCO$  is decreased. Hypoxaemia, with an increased alveolar-arterial  $PO_2$  difference, may occur [125,144] and type II respiratory failure has been described [145]. IgE concentrations are normal or only slightly increased [126,135].

### Diagnosis

In most cases the radiographic and clinical appearances are so typical that a trial of corticosteroid therapy is indicated [120]. When there is doubt about the diagnosis, bronchoalveolar lavage or even open lung biopsy may be indicated to establish the diagnosis and exclude other possibilities.

**Fig. 38.4** Chest film of patient with chronic eosinophilic pneumonia before treatment with corticosteroids showing mainly peripheral areas of consolidation. His eosinophil count was  $2 \times 10^9/L$ .

### Treatment

Typically, clinical improvement occurs rapidly within 2–3 days of instituting therapy with 30–40 mg of prednisolone daily. Radiographic clearing should be evident after 2–3 days and the chest film is usually normal within 10–14 days [120]. Occasionally higher doses of prednisolone are required. Decrease in the dose and withdrawal of steroids should be possible after recovery, although recurrences

requiring reinstitution of steroid therapy may occur. It is recommended that steroids should be continued in a maintenance dose of 5–20 mg daily for at least 6 months. The author usually tapers the dose slowly from the initial treatment dose over this period of time. A report of 12 cases followed for a mean interval of 10 years identified relapse (often multiple) in a majority when corticosteroids were discontinued or tapered; prompt resolution occurred with the reinstitution of therapy. A minority remained disease-free when treatment was discontinued [135]. Clearly, an attempt should be made to discontinue treatment, provided the possibility of recurrence is borne in mind.

### **Polyarteritis nodosa and allergic granulomatosis (Churg–Strauss syndrome)**

#### **Definition**

Classical polyarteritis nodosa is characterized by a necrotizing vasculitis of small and medium-sized muscular arteries with involvement of multiple organ systems. Eosinophilia and granulomas are not characteristic of this disease and the lung and spleen are usually not involved [146–149]. Allergic granulomatosis (Churg–Strauss syndrome [146–148]) strongly resembles classical polyarteritis nodosa but has some obvious distinguishing features. An allergic diathesis, particularly severe asthma, is usual and, unlike the classical disease, lung involvement is a *sine qua non* of this syndrome. Other features include peripheral blood eosinophilia, eosinophilic tissue infiltration and granulomatous reactivity. Histologically, in addition to involvement of small and medium-sized muscular arteries, small vessels such as capillaries and venules may be affected by the pathological process. To complicate matters further an ‘overlap syndrome’, with features of both classical polyarteritis nodosa and allergic granulomatosis, is now recognized.

#### **Aetiology**

In cases with pulmonary involvement the sex incidence is approximately equal. The disease is found at all ages, with a mean age at onset of 38 years [31]. The disease may prove to be an immune complex vasculitis due to type III hypersensitivity to an external or internal antigen. Immune complexes have certainly been demonstrated with vasculitis and hepatitis B antigenaemia [150,151]. When immune complexes are trapped on a vessel basement membrane, complement is activated leading to an accumulation of polymorphonuclear leucocytes that cause damage and necrosis of the vessel wall by release of lysosomal enzymes. An alternative cell-mediated mechanism, which would explain the granuloma formation, postulates that macrophages are recruited to the vessel wall by

lymphokines released from sensitized lymphocytes. The macrophages may be activated (possibly by immune complexes) to release lysosomal enzymes, with resultant vessel wall damage; at the same time the macrophages have the potential to transform into epithelioid cells with the formation of granulomas [146].

Studies using monoclonal antibodies have revealed large amounts of ECP and eosinophil protein X in the granulomas of Churg–Strauss syndrome. Activated and degranulating eosinophils are a feature of the pathological lesions and it would appear that these cytotoxic eosinophil proteins may play an active part in the development of the lesions [152].

In one large series [149] approximately one-quarter of the patients had received various drugs, most often sulphonamides, before the onset of their illness, and it has been suggested in the past that a real decrease in the incidence of polyarteritis was associated with a decline in the use of sulphonamides [153].

#### **Pathological features**

Macroscopically, necrotic lesions, infarcts and bronchiectasis may be found in the lungs [147–149]. The necrotic lesions may be nodular and cavitated and may give rise to areas of intra-alveolar haemorrhage. Microscopically, the necrotic areas are surrounded by giant cells, lymphocytes, plasma cells and neutrophils and there may be diffuse eosinophil infiltration. In the pulmonary arteries and veins, there is proliferation of intimal connective tissue and infiltration with eosinophils and neutrophils. The media particularly of the arteries often shows fibrinoid change, sometimes with giant cells, and granulomatous reactions are found in connective tissue and vessel walls (Fig. 38.6).

#### **Clinical features**

Patients with Churg–Strauss syndrome almost invariably have an illness presenting with respiratory symptoms [31,147,154]. These symptoms may precede other evidence of systemic involvement by a number of years. Asthma is the most common presenting symptom and is usually chronic and severe. Upper airway involvement may manifest as rhinitis, sinusitis or nasal polyps. In one series, asthma preceded the vasculitis in 80% of cases and the mean duration of this preceding asthma was 8 years [154]. Incidents of ‘pneumonia’ with cough and blood-stained sputum may occur and sputum may contain numerous eosinophils. There may be fever [154] and other systemic symptoms, including weakness, malaise, arthralgia, night sweats, myalgia and loss of weight. A diagnosis of tuberculosis may initially be considered (Fig. 38.7).

In patients with involvement of other systems, symptoms and signs referable to these systems may be noted.

**Fig. 38.6** Small artery from necropsy specimen in patient with Churg–Strauss syndrome showing a florid necrotizing vasculitis with thrombosis and inflammatory cells in the occluded lumen (haematoxylin & eosin  $\times 170$ ).

These include heart failure, pericarditis and hypertension [155,156]. The gastrointestinal tract may be involved, resulting in abdominal pain, diarrhoea or bleeding [31]. Skin lesions are found in 70% of patients and may include petechiae, purpura, nodules or urticaria. Mononeuritis multiplex occurs in 66% and central nervous system involvement in 29% [31]. Reversible exophthalmos and hearing loss have been reported [157].

### Radiographic features

In the chest film, patchy pneumonic consolidation often resembling chronic eosinophilic pneumonia is found and the shadows may have the same migratory characteristics [154,158,159]. Diffuse interstitial shadows may occur (Fig. 38.7) and nodules, which may cavitate, are frequently seen. Pleural effusion has been recorded. The clinical and radiographic presentation may be confused with tuberculosis.

### Other investigations

Anaemia and leucocytosis are common and eosinophilia occurs [31,147,154], with absolute counts higher than  $5 \times 10^9/L$  in one series [149]. The ESR is usually markedly elevated and a high plasma globulin fraction is found. IgE levels are elevated in most patients [160,161]. Anti-neutrophil cytoplasmic antibodies of the *P* type are commonly present [162,163]. Pulmonary function tests show obstructive defects. The diagnosis is established by biopsy of involved organs. Transbronchial lung biopsy is inadequate and open or thoracoscopic lung biopsy is preferred.

### Treatment

Without treatment the course of the disease is progressive,

with exacerbations and partial remissions. In one series [149], 70% of those beginning with a respiratory illness were dead within 1 year. The treatment of choice is corticosteroids and large doses, such as 40–60 mg of prednisolone daily, are often needed initially and should be continued for several weeks to ensure remission of the vasculitis [31]. With remission of symptoms and establishment of a normal ESR, the dose can be tapered to a maintenance level which, typically, is continued for at least 1 year. In the Mayo Clinic series of 30 cases treated with high-dose corticosteroids, 15 patients nevertheless died with a mean time to death of 4 years [154]. In cases resistant to corticosteroid therapy, remission may be induced by the addition of azathioprine [164] or cyclophosphamide [165]. Methylprednisolone pulse therapy has been used successfully in patients failing to respond to oral prednisolone [166,167].

### Hypereosinophilic syndrome

This rare syndrome is characterized by marked peripheral blood eosinophilia and by eosinophilic infiltration of many organs in the absence of a known cause [168,169]. Suggested criteria for the diagnosis are:

- 1 persistent peripheral eosinophilia of greater than  $1.5 \times 10^9/L$  for longer than 6 months;
- 2 signs and symptoms of organ involvement;
- 3 no evidence of allergic, parasitic, vasculitic, neoplastic or other known cause of eosinophilia [168].

### Clinical features

The cause of the hypereosinophilic syndrome is unknown. Onset is usually in the third or fourth decade and males predominate [170]. The clinical presentation may

**Fig. 38.7** Churg–Strauss syndrome: the patient presented with fever, arthralgia, dyspnoea and haemoptysis. Chest film showed diffuse patchy consolidation (a) that responded rapidly to high-dose corticosteroids (b).

superficially resemble that of eosinophilic pneumonia, with systemic symptoms including fever, night sweats, anorexia, malaise, weight loss, pruritus and cough. However, a profound peripheral eosinophilia is usually present, with eosinophils comprising 30–70% of a normal or increased white count [168]. IgE levels are often high. Eosinophils are present in large numbers in the bone marrow, and eosinophilic metamyelocytes, myelocytes

and even myeloblasts may be found in the peripheral blood [168].

Pulmonary involvement, typically presenting as cough that is worse at night, may be seen in up to 40% of patients. Chest radiographs may show interstitial infiltrates and pleural effusions are common [168]. Bronchoalveolar lavage shows high percentages of eosinophils [171].

Cardiovascular involvement is the major cause of morbidity and mortality [172,173]. Endocardial fibrosis, restrictive cardiomyopathy, valvular damage and mural thrombus formation may occur. Arterial (and venous) thromboembolic disease is common. Splinter haemorrhages are frequent but infarction of the kidney, spleen, cerebrum and retina are also seen; deep vein thrombosis and other peripheral vascular occlusions such as femoral artery embolism have been recorded. Finally, eosinophil infiltration of the kidney, skin, gastrointestinal tract, joints and muscles may also give rise to symptoms.

Serum levels of interleukin-2 receptors appear to correlate with disease activity and severity [174].

### Treatment

About 50% of patients respond to extended initially high-dose oral corticosteroid therapy beginning with 60 mg of prednisolone daily [175]. It has been suggested [175] that treatment should be reserved for those with demonstrable end-organ damage due to the hypereosinophilia. Other drugs that have been used successfully include hydroxycarbamide (hydroxyurea), cyclophosphamide, azathioprine, interferon  $\alpha$ , cyclosporin, etoposide and vincristine [168,170,176–178].

## Acute eosinophilic pneumonia

### Diagnostic criteria

This relatively new entity was first described in 1989 [179,180]; the diagnostic criteria are given in Table 38.4 [31].

### Clinical features

Patients may be of any age or sex and typically present with an acute febrile illness of several days' duration with associated myalgia, pleurisy and hypoxaemia often requiring ventilatory support. There may be a history of allergic rhinitis [136]. Physical examination confirms fever, respiratory distress and diffuse inspiratory crepitations, usually without wheeze, on auscultation. There may be signs of pleural effusion.

**Table 38.4** Diagnostic criteria for acute eosinophilic pneumonia [31].

---

Acute febrile illness of <5 days' duration
Hypoxaemic respiratory failure
Diffuse alveolar or mixed alveolar interstitial chest radiographic infiltrates
Bronchoalveolar lavage eosinophils >25%
Absence of parasitic, fungal or other infection
Prompt and complete response to corticosteroids
Failure to relapse after discontinuing steroids

---

### Radiology

The chest radiograph typically shows diffuse alveolar or alveolar–interstitial infiltrates. Peripheral infiltrates (unlike chronic eosinophilic pneumonia) are unusual. Kerley B lines are common. Small to medium pleural effusions are often seen and, if tapped, show a high percentage of eosinophils [181].

### Other investigations

Peripheral blood eosinophilia is not usually found; in striking contrast, the eosinophil count in bronchoalveolar lavage fluid is high with an average of 42% in one early series [179]. Serum IgE levels have been elevated in some but not all patients. Pulmonary function studies show a restrictive pattern with a low diffusing capacity [181]. Lung biopsy confirms the presence of a non-vasculitic eosinophilic pneumonia [182].

### Treatment

Hypoxaemia may be severe enough to require ventilatory support. Treatment is with high-dose (60–125 mg daily) prednisolone or methylprednisolone until respiratory failure resolves. The lowest effective initial dose has yet to be determined, although it has been established that continuation therapy with 40–60 mg daily for 2–4 weeks with a subsequent tapering of dosage to zero over a further 2–4 weeks does not occasion relapse. The cause of this condition, if indeed it is a separate entity, remains to be determined. An acute hypersensitivity phenomenon has been suggested [179].

# SARCOIDOSIS

A. GORDON LEITCH

## Definition

Until the precise cause of sarcoidosis is known, the following descriptive paragraph prepared by the Seventh International Conference on Sarcoidosis will continue to be useful in place of a definition:

Sarcoidosis is a multisystem granulomatous disorder of unknown aetiology most commonly affecting young adults and presenting most frequently with bilateral hilar lymphadenopathy, pulmonary infiltration and skin or eye lesions. The diagnosis is established most securely when clinicoradiographic findings are supported by histological evidence of widespread non-caseating epithelioid granulomas in more than one organ or a positive Kveim–Siltzbach skin test. Immunological features are depression of delayed-type hypersensitivity, suggesting impaired cell-mediated immunity, and raised or abnormal immunoglobulins. There may also be hypercalciuria with or without hypercalcaemia. The course and prognosis may correlate with the mode of onset: an acute onset with erythema nodosum heralds a self-limiting course and spontaneous resolution, while an insidious onset may be followed by relentless progressive fibrosis. Corticosteroids relieve symptoms and suppress inflammation and granuloma formation [1].

Since this description was published in 1976, substantial advances in the understanding of the immunology of sarcoidosis have resulted from the application of the technique of bronchoalveolar lavage (BAL) via the fiberoptic bronchoscope. These advances are described in detail later in the chapter and considerably enhance the outline of the immunological abnormalities given in the above description.

## Historical background

In 1936 Hunter [2] suggested that a case seen by Hutchinson in 1869 and reported in 1877 [3] may have been an example of the condition subsequently described by

Hutchinson in 1898 as Mortimer's malady. It now seems clear that Hutchinson did not himself identify the 1869 case as one of Mortimer's malady, making any claim to priority dubious [4]. In 1889 Besnier gave a detailed account of a patient with the clinical features of lupus pernio [5] and 3 years later Tenneson [6] described a similar case in which the histology was studied and the typical granulomatous lesion found.

Hutchinson in 1898 described skin lesions that principally affected the face, arms and hands and which were referred to for a long time as 'Mortimer's malady', a tribute to the lady who was the first of a series of patients with these manifestations. In his comment on four cases, Hutchinson showed remarkable foresight when he wrote 'the truth is probably that the various pathogenetic influences are capable of the most various combinations and that we have, on all sides, connecting links between maladies which have gained distinctive names'. Over the next few years, Boeck, Heerfordt and Jungling, unaware of the unitary nature of the disease, described clinical pictures that were regarded as disease entities and given eponymous designations [3,5,7–15] (Table 39.1). The term 'sarcoid' was introduced by Boeck because of a superficial resemblance of a skin lesion to sarcoma.

In 1914 Schaumann recognized the relation between the various recorded presentations and in an essay entitled 'Sur le lupus pernio' (for some reason not published until 1934) emphasized the systemic nature of the disease [13]. In 1917 he suggested the term 'lymphogranuloma benigna' [14]. This was something of a euphemism considering that Schaumann himself stated that 'the most usual course is that a classical tuberculosis manifests itself in the lungs, peritoneum, etc. causing death'. He clearly favoured a tuberculous aetiology. He felt that the benignity of the disease 'should be regarded as only relative and referred to the protracted course of the disease and, for a long time, its insignificant effect on general condition'. Apart from tuberculosis, death frequently occurred from 'debility, usually combined with severe dyspnoea and cardiac weakness'. It should, of course, be remembered

**Table 39.1** Historical background of sarcoidosis.

Date	Author	Description
1869	Hutchinson [3]	'Anomalous disease of skin of fingers' (papillary psoriasis)
1889	Besnier [5]	Lupus pernio
1898	Hutchinson [7]	Lupus vulgaris multiplex non-ulcerans (Mortimer's malady)
1899	Boeck [8]	Multiple benign sarcoid
1904	Kriebich [9]	Bone changes ('chronic osteomyelitis') in cases of lupus pernio
1905	Boeck [10]	Benign miliary lupoid
1906	Darier & Roussy [11]	Subcutaneous sarcoid
1909	Heerfordt [12]	Uveoparotid fever
1914	Schaumann [13]	'Sur le lupus pernio'
1917	Schaumann [14]	Benign lymphogranuloma
1920	Jungling [15]	Ostitis tuberculous multiplex cystica
1940+		Universal acceptance of term 'sarcoidosis'

that it was mainly the chronic form of the disease that was being recognized and that many cases were erroneously treated in tuberculosis sanatoria with inevitable exposure to infection.

With the introduction of mass miniature radiography during the Second World War, it soon became apparent that the hilar glands and lungs were affected, that many cases were asymptomatic and that spontaneous resolution was the rule in the vast majority of cases.

The relationship between erythema nodosum, bilateral hilar lymphadenopathy and sarcoidosis was first properly defined by Lofgren to give us the syndrome that bears his name [16,17]. In the 1940s the term 'sarcoidosis' was universally accepted as the name for this condition. It soon became obvious that many patients with sarcoidosis had previously been wrongly classified as tuberculosis, a situation that probably still exists in many developing countries today [18].

## Epidemiology

### Incidence and prevalence

There are considerable difficulties in obtaining reliable prevalence figures for sarcoidosis that allow valid comparisons between different geographical areas. The nature of the disease is such that many asymptomatic cases escape detection, particularly in countries where radiographic screening programmes are not available. Presentation may be to any one of a wide range of medical specialties, with all the resulting problems of collating medical records. Finally, there may be different degrees of awareness of the disease in different countries and probably also variation in diagnostic criteria.

### Mass radiography studies

The results of an international study of pulmonary sarcoidosis detected by mass radiography are shown in Table 39.2 [19]. There is considerable disparity in prevalence figures for the various countries, with a range from 0.2 per 100 000 in Poland and Brazil to 64 per 100 000 in Sweden. A more recent study from Sweden in which 64% of the population over 15 years were screened at 3-yearly intervals gave a prevalence of 19 per 100 000, which extrapolated to 24 per 100 000 assuming 100% screening [20,21]. A similar recent survey from Finland reported a prevalence of 15 per 100 000 in those over 15 years [22]. The wide range of reported prevalences may reflect a distinctive geographical pattern for the disease and suggest that sarcoidosis is an entity determined by a specific environmental factor or factors. Other factors that may contribute to geographical differences, other than the sources of error referred to in the introduction, are the age and sex structure of the population, ethnic groups and genetic factors, which are discussed later in this section.

### Data from diagnostic records

Where special efforts are made to identify all cases presenting to medical practitioners including general practitioners, the incidence is more likely to reflect the true state of affairs. A recent study of this kind in the Isle of Man [23] found a mean annual incidence of 15 per 100 000 over the years 1977–83 compared with 3.5 per 100 000 in the preceding 15 years when less intensive searching had been carried out.

A similar intensive study was conducted in four areas of the UK by the British Thoracic and Tuberculosis Association from 1961 to 1966 in predominantly Caucasian populations [24]. This found a range of annual incidences of 2.1–4.5 per 100 000 for men and 3.5–4.5 per 100 000 for women, with an increase in incidence from north to south. Peak incidence was in the age group 25–34 years. In the US Army, based on records of disability and death, the incidence of cases was found to be 11 per 100 000, with the peak incidence in the 25–29 age group [25]. The rates for Blacks were 16 times the rates for all other groups.

In developing countries, comparable figures are not easily obtained but where the disease has been sought, as in the Bantu, it has been found and is 10 times more common than in the white population [18]. In other countries where the incidence is believed to be low, such as China, South-East Asia and South America, it is still not clear whether this represents a real finding or is the result of a combination of confounding factors, such as misdiagnosis, inadequate diagnostic facilities and continuing confusion with tuberculosis [4].

Despite geographical variations in incidence of disease,

the pattern of disease in different countries is remarkably similar [26] (Table 39.3), with a few important exceptions. Patients most commonly present with respiratory symptoms, ocular or skin disease or because of a routine chest radiograph.

### Age and sex incidence

Most studies have shown the highest incidence in the third and fourth decades [24–30], with a variable female predominance [27,31,32]. Children and the aged are not immune but the disease is uncommon at the extremes of life. It is of interest that in Japan, where children over

\*Reticuloendothelial, spleen and peripheral lymph nodes.

8 years of age are included in a comprehensive mass radiography programme, the prevalence rates for school-children have ranged from 1 to 2 per 100 000 [33].

**Ethnic factors**

As already mentioned, sarcoidosis is 16 times more common in Black compared with non-Black US soldiers and is also much commoner in the Bantu compared with the white South African population [18,25]. In London, the annual incidence of sarcoidosis was shown to be 20 per 100 000 in Black people per 100 000 in Asians and 1.5 per 100 000 in Caucasians [34]. As reported previously from London and the USA, erythema nodosum is relatively uncommon in Black people, who tend to have more extrathoracic and severe disease requiring steroid therapy [35,36]. The clinical picture in Asians and Puerto Ricans more closely resembles that in West Indians and Black people than in Caucasians [34,36].

**Familial factors**

A British Thoracic Society Research Committee investigation reported 59 families in Britain with more than one case of sarcoidosis [37]. There were three families with more than two cases, giving a total of 62 instances made up of five twins (four monozygotic and one dizygotic), 28 siblings, 22 parent–child and seven husband–wife. The total number of patients was 121, comprising 46 males and 75 females. A review of 160 published instances of familial sarcoidosis also showed a marked excess of monozygotic over dizygotic twins (13:1), supporting a genetic influence. The most striking features of these were the significantly larger proportions of like sex over unlike sex pairs among both siblings and parent–child instances and the excess of mother–child over father–child associations. The conclusions were valid even when account was taken of

the known higher incidence of sarcoidosis in females [24]. Other published reports also show a marked excess of mother–child over father–child relationships but only a slight excess of like sex over unlike sex pairs [38,39]. An Irish study described 114 index cases of sarcoidosis with a total sibling pool of 534 [40]. Of the index cases, 11 had siblings with a diagnosis of sarcoidosis giving a prevalence of sarcoidosis among siblings of 2.2%. This may suggest that genetic influences are determinants for the development of sarcoidosis. Nevertheless, the demonstration in the Isle of Man of space–time clustering of the disease is also consistent with sarcoidosis being a communicable disease [41,42].

**Human leucocyte antigens**

A number of studies of human leucocyte antigens (HLA) in sarcoidosis have been undertaken and the evidence that HLA type does not influence susceptibility to sarcoidosis is reviewed by Scadding and Mitchell [4].

There is evidence that HLA type does influence the pattern of disease. A high incidence of HLA-B8 has been found in London patients with arthropathy or erythema nodosum [43]. Two other studies have confirmed this association [44,45]: of 107 white patients with sarcoidosis, 40% had HLA-B8, while the percentages among those with arthropathy and erythema nodosum were 62% and 89% respectively. In 19 Swedish patients with acute-onset sarcoidosis (all having bilateral hilar lymphadenopathy and arthropathy and seven erythema nodosum), HLA-B8 was present in 67% and HLA-DR3 in 90% compared with frequencies of 24% and 26% in the Swedish population [46]. These authors noted that HLA-B1, -B8 and -DR3 occur in linkage disequilibrium and that this haplotype has been associated with abnormal immune responsiveness [46]. A more recent study in English Caucasians and Black West Indians with sarcoidosis has found an

increased frequency of HLA-Cw7 in the Caucasians and that HLA-DR3 and the B8/Cw7/DR3 haplotype were associated with a good prognosis in the Caucasians. No significant associated good prognostic indices were found in the West Indians [47]. In Japan, increased frequencies of HLA-DRw52 and -DR5J have been found in sarcoidosis patients, the latter being especially significant in unresolved cases [48–50].

It would appear from studies to date that HLA-B8, -Cw7 and -DR3 are associated with the hilar lymphadenopathy/erythema nodosum/arthopathy form of the disease, which carries a good prognosis. This association may explain the correlation between the frequencies of HLA-B8 and sarcoidosis with erythema nodosum in different populations, for example the frequency of HLA-B8 is 29% in London, 16% in New York and 2% in Tokyo and the percentage of patients with sarcoidosis and erythema nodosum in these cities is 31%, 11% and 4%, respectively [45].

## Aetiology

The cause of sarcoidosis is unknown. A number of aetiologies, including exposure to pine pollen or beryllium and infection with *Mycobacterium*, viruses and fungi, have been suggested and rejected as reviewed by Scadding and Mitchell [4]. Animal inoculation studies have suggested the possibility of an unidentified transmissible agent [51], as have the Isle of Man studies [41,42].

### Possible role of an unidentified transmissible agent

In 1969 Mitchell and Rees [51] reported the results of a controlled experiment in which an attempt was made to demonstrate a transmissible agent from sarcoid material. Sarcoid and non-sarcoid lymph node homogenates were inoculated into the footpads of normal and immunologically deficient mice. The early and late changes in the footpads were assessed microscopically. A substantial proportion of the mice receiving sarcoid homogenate showed the histological characteristics typical of sarcoidosis in humans, which evolved fully after a period of 6–8 months following inoculation. Kveim tests were carried out and positive results were confined to a proportion of those mice given sarcoid homogenates and were all associated with sarcoid granulomas in the footpad. Conversely, the inflammatory lesions seen in the footpads of mice inoculated with non-sarcoid homogenates were negative. The authors concluded from this preliminary work that an agent, as yet unidentified, may have been transmitted to the mice from human sarcoid tissue; however, an alternative explanation might be that they were demonstrating the reactivity of mice to a factor, or factors, common to granulomatous reactions in general. They obtained

similar results with tissues from Crohn's disease [52]; normal human lymph node extracts used as controls did not give rise to footpad granulomas or positive Kveim tests.

The work on induction of granulomas in mice by injection of human sarcoid and ileitis homogenates has been confirmed and extended by other workers and allows the speculation that the affected lymph nodes of sarcoidosis and regional ileitis and ileitis bowel may harbour transmissible agents that play a role in granuloma formation [53–56].

Later work by Mitchell and Rees [55] found that granulomas could be produced in normal or immunologically deficient mice by footpad, intraperitoneal or intravenous injections with fresh whole sarcoid homogenates, fresh supernatants or fresh 0.22- $\mu$ m filtered supernatants. In contrast, no granulomas were seen in response to identically prepared non-sarcoid tissue homogenates. Successful passage was also achieved following the inoculation of both filtered and unfiltered 'sarcoid' mouse tissue homogenates into secondary hosts [56]. The agent could be inactivated by autoclaving or by irradiation with cobalt-60 [57].

In 1983 Mitchell and Rees [58] reported that although the human tissues used had been negative microscopically and culturally for *Mycobacterium*, acid-fast bacilli had been seen in granulomatous tissues of mice passaged from sarcoid tissues of six patients. These were found in mouse lungs and spleen 17 months or more after the injection of homogenate or supernatant filtrate of mouse granulomatous tissue on first to third passage from the original injection of human sarcoid tissue 3–9 years before. *Mycobacterium tuberculosis* was grown from pooled homogenates of lungs and spleen from mice in two of these serial passages. This has fuelled interest in the suggestion originally made by Burnet in 1959 [59] that a protoplast or L form of the tubercle bacillus may be a cause of sarcoidosis.

The implication that *M. tuberculosis* might have a pathogenic role in sarcoidosis has been further explored by sophisticated and very sensitive molecular biological techniques, including polymerase chain reaction (PCR) for the mycobacterial DNA sequence known as IS6110 [60–62]. In one UK study, *M. tuberculosis* DNA was found by PCR in half the patients with sarcoidosis, one-third of the patients with inactive tuberculosis and in 60% of patients with active tuberculosis [61]. In contrast, a meticulously controlled North American study found DNA from *M. tuberculosis* in only a minority of patients with sarcoidosis [62]. An accompanying editorial [63] emphasizes that for most patients with sarcoidosis PCR analysis of their cells or tissues is unable to detect any DNA from *M. tuberculosis* at a level of sensitivity of 15 organisms per million human cells. The sensitivity of PCR for *M. tuberculosis* is fraught with hazard, particularly with regard to

contamination [63]. At present, the jury does not have enough evidence to implicate mycobacteria in sarcoidosis. It may be that detected DNA simply represents previous mycobacterial infection. Studies in patients with sarcoidosis from countries with dramatically differing prevalences of tuberculosis may resolve this issue.

### Transplantation and sarcoidosis

Recurrence of disease in the pulmonary allografts of patients treated for end-stage pulmonary sarcoidosis by lung transplantation has been recorded [64,65] and is consistent with current thinking about the immunopathogenesis of the disease (see below). Recurrence was limited to transbronchial biopsy evidence of granulomas within months of transplantation in one report [64] and to radiological and biopsy evidence of sarcoid infiltrates 13 months after transplantation in the other [65]. Disease

recurred despite immunosuppression and responded to an increased dose of oral prednisolone [65].

### Pathology

The histological reaction in active sarcoidosis (Figs 39.1 and 39.2) consists essentially of nodular collections of large closely packed, pale-staining histiocytes (epithelioid cells). In early lesions the nodules are all characteristically at the same stage of development. A few multinucleated giant cells are usually seen among the histiocytes and some lymphocytes are often present at the periphery of the nodule. Three different types of inclusion bodies may be found in the cytoplasm of the epithelioid and giant cells.

1 Schaumann bodies, which are round or oval and vary in size from that of a leucocyte to about 100  $\mu\text{m}$  in diameter. The larger of these bodies (sometimes referred to as con-

**Fig. 39.1** Resected lung from patient with sarcoidosis: (a) small, compact epithelioid and giant cell interstitial granulomas (haematoxylin & eosin  $\times 15$ ); (b) epithelioid and giant cells in the granuloma (haematoxylin & eosin  $\times 35$ ).

**Fig. 39.2** Lymph node from same patient as in Fig. 39.1 showing multiple non-caseating granulomas (haematoxylin & eosin  $\times 35$ ).

**Fig. 39.3** Multinucleate giant cell from a sarcoid granuloma containing a typical asteroid body (haematoxylin & eosin  $\times 350$ ).

choid bodies) seem to be formed of basophilic concentric lamellae that appear to contain calcium and iron.

2 Doubly refractile crystalline inclusion bodies are 1–20  $\mu\text{m}$  in diameter and may take up stains for calcium and iron.

3 Asteroid bodies consist of a central mass 2.3–3  $\mu\text{m}$  in diameter with radiating straight or centred spinous projections, the whole being 5–25  $\mu\text{m}$  in diameter (Fig. 39.3).

Necrosis does not occur in the sarcoid nodule, or is only minimal. In consequence the reticulin between the histiocytes and around the nodules remains intact. Where present, this is an important point of distinction from the tuberculous follicular reaction. No acid-fast bacilli are found in the sections or can be cultured from them, with rare exceptions that may be explained by pre-existing, coexisting or consequential independent infection.

The epithelioid cells are large mononuclear cells about 20  $\mu\text{m}$  in diameter with round or oval nuclei and are derived from macrophages. They are poorly phagocytic but highly secretory, producing acid phosphatase, cathepsin,  $\beta$ -glucuronidase, collagenase, elastase, cytolytic factors, lysozyme and angiotensin-converting enzyme [66–71]. Giant cells are up to 300  $\mu\text{m}$  in diameter, containing as many as 30 nuclei usually arranged peripherally. Giant cells occur by the fusion of macrophages, which are constantly arriving, dividing and ageing. Spector [72] points out that the macrophages in sarcoid granulomas are not only metabolically active but are turning over rapidly, in contrast to macrophages in granulomas produced by relatively inert materials such as carbon. Soler and colleagues [73] have studied serial sections of a pulmonary sarcoid granuloma by electron microscopy and noted that epithelioid cells tend to be central and

macrophages peripheral. This supports Spector's concept of the constant arrival of macrophages into a granuloma pool of mixed young and old macrophages, epithelioid and giant cells. The inclusion bodies are all non-specific end-products of the active metabolism and secretion that has taken place. As the lesion ages, reticulin fibres ramify between epithelioid cells, gradually thicken and eventually become converted into collagen. It loses its outline and becomes a solid amorphous eosinophilic mass of hyaline material.

The lymphocytes associated with the granulomas are larger than usual and morphologically appear activated [73]. Lymphocyte accumulations are more common in active lesions, when they are predominantly CD4 T-helper cells. As activity declines CD8 T-suppressor cells become more common [74]. Relatively large numbers of B cells and plasma cells are also present, suggesting that immunoglobulin production is also occurring at sites of granuloma formation [75].

Sarcoid follicles may resolve completely. When healing occurs in long-standing cases, the cellular nodules become replaced by fibrous tissue. In chronic sarcoidosis, follicles with the characteristic appearance may exist among masses of avascular fibrous tissue. Sclerosis of a follicle usually begins at the periphery with the formation of discrete hyaline clumps, which fuse to girdle the nodule; hyalinosis proceeds in a centripetal fashion until the follicle is wholly involved [76].

Several electron microscope studies have been made of Kveim and sarcoid lesions [77–82]. The epithelioid cells are seen by the electron microscope to be closely packed. At their margin, there is much plication and interdigitation of the various cells [78]. All the cells have large numbers of mitochondria indicating high metabolic activity. Certain cells show small dark bodies that are some kind of granule and may include large, pale vacuole-like bodies which probably contain protein. Very dark fibrillar material between the cells has the appearance of collagen. The giant cells show irregular peripheral nuclei and have numerous mitochondria, consistent with high metabolic activity.

The histological features of the sarcoid lesion are not specific and may occur in tuberculosis as well as leprosy, tertiary syphilis, brucellosis, primary biliary cirrhosis, hypogammaglobulinaemia, fungal infection and berylliosis [83–86]. A localized sarcoid reaction of the same histological pattern is sometimes observed in the vicinity of lesions due to carcinoma (especially in regional lymph nodes), lymphomas, fungal infections [87], trauma and chemical injury. Zirconium, a constituent of deodorant sticks, has been shown to cause a chronic axillary dermatosis via the development of a specific hypersensitivity reaction. These local tissue sarcoid reactions can usually be distinguished from systemic sarcoidosis by the absence of depressed or negative delayed-type hypersensitivity

reactions and a negative Kveim test [88]. Lack of evidence of sarcoid lesions in other tissues or organs is another distinguishing feature.

## Immunology

The granulomas of pulmonary sarcoidosis are now thought to be the consequence of activation of lymphocytes and macrophages within the lung, with resultant release of potent mediators that play a critical part in the pathogenesis of the disease [89–92] (Fig. 39.4). The stimulus for activation is unknown, although the state of activation of lung mononuclear cells is characteristic of that due to antigen stimulation and it may be that an unknown antigen is involved. In support of an unknown antigen is the finding of circulating immune complexes, particularly in the early stages of the disease [93–97]. Major advances in understanding the pathogenesis of sarcoidosis have come from studies on cells obtained by BAL using the fiberoptic bronchoscope [98]. Studies that have compared lavage with biopsy cell populations, including typing of T cells, suggest that cells obtained by lavage are representative of those found in biopsies from the same patient [99–101]. The total number of cells recovered at BAL is increased, with striking increases in the absolute numbers of macrophages and lymphocytes, although the percentage of macrophages decreases while the lymphocyte percentage increases (Fig. 39.5).

## Lung lymphocytes

In active sarcoidosis the vast majority of lavage lymphocytes are T lymphocytes and of these most are CD4 T-helper cells, these cells outnumbering T-suppressor cells by 10 to 1. The T cells are activated, as demonstrated by increased rosetting with sheep erythrocytes at 37°C, and have been shown to release a number of lymphokines [101–105]. These include interleukin (IL)-2, a 15-kDa glycoprotein known to induce T-cell activation and replication [106]. Such activated T cells release other lymphokines that produce polyclonal B-cell activation and increased immunoglobulin production resulting in hyperglobulinaemia [106–108]. In addition, activated T cells release monocyte chemotactic factor and migration inhibition factor that act together to attract, immobilize and activate monocytes, the building blocks of granuloma formation [109].

## Lung macrophages

The macrophage population in the lung is increased in active sarcoidosis and consists of alveolar macrophages and young macrophages that are probably freshly recruited monocytes [90]. The macrophages are activated, as shown by increased uptake of gallium-67 [110] and the

Fig. 39.4 Pathogenesis of granuloma formation (see text for explanation).

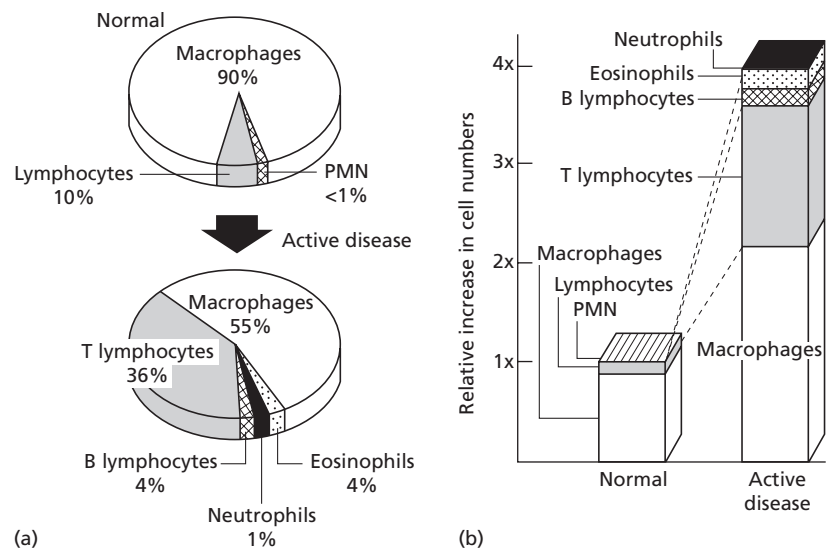

Fig. 39.5 Proportions (a) and total numbers (b) of cells obtained by bronchoalveolar lavage in normal subjects and in active sarcoidosis. (From Crystal *et al.* [90].)

release of mediators. IL-1 is released and leads to T-cell activation [111,112]. In addition, the release of interferon  $\gamma$ , fibronectin and alveolar macrophage-derived growth factor may promote fibroblast recruitment, attachment and proliferation and lead to fibrosis [89,113]. Transforming growth factor  $\beta_1$  can also be demonstrated in the sarcoid granuloma [114].

## Blood

In striking contrast to the findings in the lung, peripheral blood in sarcoidosis usually shows a lymphopenia with a lower than normal ratio of T-helper to T-suppressor cells [115–117]. Where the ratio of T-helper to T-suppressor cells is low, blood lymphocytes show diminished phytohaemagglutinin responsiveness [116]. These findings may explain the depression of delayed-type hypersensitivity

that has long been noted as a feature of sarcoidosis. Thus, reactions to tuberculin, mumps virus antigen, *Candida albicans* antigen and trichophytin have all been shown to be depressed in patients with sarcoidosis [118–122]. The hyperglobulinaemia that is a feature of chronic active sarcoidosis is largely due to overproduction of predominantly IgG and IgA at sites of disease activity [95,108].

### Modes of presentation

The diversity of the possible clinical manifestations is such that a practitioner in almost any branch of medicine may be called upon to make the diagnosis. All kinds of combinations of organ involvement are possible [123] (Table 39.4). With the exception of the pleura, the serous membranes are rarely involved but only the adrenals appear to be sacrosanct. No authenticated adrenal involvement has been reported apart from a suggested but unproven case in one series [124].

Sarcoidosis would be relatively unimportant if not for the fact that it can affect vital organs in a chronic fashion, with the development of irreversible fibrosis resulting in functional impairment. Involvement of the eyes can lead to blindness and death can occur from cardiac, respiratory or renal failure.

### Thoracic sarcoidosis

#### Clinical features

The hilar glands and the lungs are the organs most commonly affected in sarcoidosis and intrathoracic involvement is the most frequent accompaniment of sarcoidosis affecting other organs (see Table 39.3). By convention thoracic sarcoidosis is classified in four stages on the basis of the appearances of the chest radiograph. Stage I represents hilar lymphadenopathy (Fig. 39.6), stage II hilar adenopathy plus pulmonary opacities (Fig. 39.7) and stage III pulmonary opacities only. Stage IV represents the development of irreversible pulmonary fibrosis.

#### Hilar lymphadenopathy

Enlargement of hilar lymph glands with or without paratracheal lymphadenopathy is the commonest manifestation of sarcoidosis (Fig. 39.6). Usually, the glands are bilaterally and symmetrically involved, although rarely hilar enlargement may appear unilateral [125,126]. Many cases of hilar lymphadenopathy due to sarcoidosis undoubtedly go unrecognized because of the absence of symptoms.

In the UK, the most common association that may suggest the diagnosis is erythema nodosum [127]. Sarcoidosis is now the most likely cause of erythema

nodosum in the 20–40 age group in this country and its occurrence should always prompt further investigation by chest radiography. The association of erythema nodosum with sarcoidosis varies throughout the world. It is common in Scandinavia [128] and the UK but is an unusual manifestation in the USA in the white as well as the black population. In North America a generation ago erythema nodosum was apparently equally uncommon as a complication of primary tuberculosis [129]. In a worldwide study of sarcoidosis, erythema nodosum was more commonly the mode of onset in the three British series than elsewhere, with a frequency of about one-third of all presentations compared with about 10% elsewhere [26]. At the extremes, the incidence in Edinburgh was 33% and in Tokyo zero.

Polyarthralgia affecting principally the knees, ankles, wrists and elbows is a frequent accompaniment of erythema nodosum and may precede the skin rash. The joint symptoms commonly subside in 3–6 weeks and joint effusions are unusual. Other presenting symptoms may include cough, dyspnoea, chest pains [130], loss of weight, malaise or excessive fatigue.

The differential diagnosis of bilateral hilar adenopathy includes tuberculosis (usually unilateral with high tuberculin sensitivity), coccidioidomycosis and histoplasmosis (USA), lymphoma (may be pain and usually systemic upset), leukaemia (blood count diagnostic), beryllium disease (occupational history), hypogammaglobulinaemia (recurrent infections) and enlarged

pulmonary arteries (characteristic appearances on CT scans).

The hilar lymphadenopathy syndrome with or without erythema nodosum is most commonly a benign manifestation. In the Edinburgh series of 230 cases of stage I disease, 80% resolved spontaneously in the first year and a further 10% showed spontaneous resolution in the second year [26]. In the worldwide study of 1865 cases of stage I disease, resolution ranged from 46 to 90% with an overall average of 65% [26]. The average time for the chest film to become normal is about 8 months [31]. About 1 in 10 cases of hilar lymphadenopathy develop chronic sarcoidosis with or without the development of further manifestations such as pulmonary opacities. In general, the older the age at onset, the greater the chance of chronicity. In a few of the cases that resolve spontaneously, transient pulmonary opacities may develop when the glands begin to regress and clear spontaneously thereafter [31]. Plaque-like or eggshell calcification may develop in persistently enlarged hilar and mediastinal glands [131,132] (Fig. 39.8).

### *Pulmonary disease*

#### *Pulmonary opacities*

Most patients with pulmonary opacities present with stage II or stage III disease, although occasionally a patient presents with chronic progressive dyspnoea due to stage

**Fig. 39.7** (a) Chest radiograph of a 25-year-old man showing bilateral hilar and paratracheal lymph node enlargement (stage I sarcoidosis). (b) The same patient 18 months later showing the development of marked pulmonary shadowing (stage II sarcoidosis).

IV disease. There are often no symptoms but there may be those already outlined for hilar adenopathy. Many types of abnormality may be seen on the chest film and these may be classified as follows:

- 1 disseminated miliary lesions (Fig. 39.9);
- 2 disseminated nodular lesions (Fig. 39.10);
- 3 linear type of infiltration extending fan-wise from the hilum;
- 4 diffuse and confluent patchy shadows;
- 5 diffuse fibrosis (Fig. 39.11);
- 6 diffuse fibrosis with cavitation [133];
- 7 diffuse ground-glass shadowing [134];
- 8 changes similar to chronic tuberculosis as regards location and distribution;
- 9 bilateral confluent massive opacities resembling areas of pneumonia;
- 10 atelectasis.

Of the varieties of pulmonary change, cavitation and atelectasis are the least common. Aspergillomas may rarely develop in cavities, apparently more commonly in men [135].

The differential diagnosis of sarcoidosis with pulmonary opacities (in which there is usually a disparity between the minimal symptoms and signs and the marked radiographic abnormalities) includes extrinsic allergic alveolitis, fibrosing alveolitis and carcinomatous infiltration (in which dyspnoea may be disproportionate to the radiographic abnormality), pneumoconiosis (occupational history), miliary tuberculosis (fever, systemic

symptoms, choroidal tubercles), metastatic malignancy (primary source may be evident), alveolar cell carcinoma (usually associated with dyspnoea if bilateral), eosinophilic granuloma (may be bone cysts on radiograph), honeycomb lung (in which evidence of mesodermal dysplasia or eosinophilic granuloma may be found) and talc granulomatosis [136].

In the Edinburgh series, 60% of pulmonary opacities showed spontaneous clearing. Half of these had cleared within 1 year, 80% within 2 years and the remaining 20% in periods from 3 to 7 years. Excluding those cases taking more than 2 years to clear, the average time for spontaneous resolution of pulmonary opacities was around 11 months.

Of patients with pulmonary opacities for whom corticosteroid therapy was considered necessary, some 50% showed clearing without any rebound phenomena after the withdrawal of treatment so that overall 80% of pulmonary opacities cleared either spontaneously or with corticosteroids and did not recur. These patients obviously belonged to a transient group of sarcoidosis and the duration of corticosteroid therapy must have coincided with the period of waning of the disease. A few patients who, for a variety of reasons, were not treated with corticosteroids early in the disease progressed to serious respiratory disability as a result of pulmonary fibrosis and many have developed the features of chronic bronchitis and airflow obstruction over the years.

In the Edinburgh series, about 1 in 10 patients with

**Fig. 39.9** Miliary shadowing on the chest radiograph of a 21-year-old woman with sarcoidosis.

**Fig. 39.10** Bilateral coarse nodular shadows in a 40-year-old man with sarcoidosis.

**Fig. 39.11** High-resolution CT of a patient with chronic sarcoidosis showing irregular diffuse fibrosis. The patient showed no response to corticosteroids.

pulmonary involvement proved to have chronic disease, as in the hilar gland group. Males fared worse than females as far as the tendency to chronicity was concerned; fortunately, the use of long-term corticosteroid therapy would seem to have prevented major disability in the majority [137]. Of the 130 patients with stage II disease and 62 with stage III disease reported from Edinburgh, radiographic resolution, spontaneous or after treatment, occurred in 79% and 42% respectively. In the worldwide study, the percentage resolution varied quite markedly from centre to centre, with overall figures of 49% for stage II and 20% for stage III disease [26].

#### *Bronchial sarcoidosis*

The bronchi may be involved in sarcoidosis through external compression by glands, resulting in atelectasis in a very few cases [138]. Sarcoid lesions may actually be present in the bronchi and it would seem that the more often bronchial lesions are sought the more commonly they are found [139,140]. Stenosis of major airways may result [141]. Bronchial hyperreactivity to methacholine may be demonstrated but not usually in patients with normal spirometric values [142,143].

#### *Pleural sarcoidosis*

Pleural sarcoidosis is uncommon but has been reported [144–146]. In one review of the literature, pleural involvement was found in 0.8% of 2410 patients from 10 large series [147]. In contrast, in a review of 227 biopsy-proven

cases of sarcoidosis, Wilen and colleagues [145] described pleural effusion and/or thickening in 23 (10%). Pleural effusions were noted in 15 and in all of these the disease progressed to stage II or beyond. However, 87% of the patients in this series were Black and such patients are well recognized to have more florid expressions of the disease.

The effusion may be a transudate or an exudate and may appear early or late in the course of the disease. It may be blood-stained and the predominant cell is usually the lymphocyte, although eosinophilic effusion has been reported [148]. Pleural biopsy may show thickened fibrous pleura interspersed with non-caseating granuloma. Rarely, presentation may occur with acute pleuritic pain [149].

#### *Rare thoracic manifestations of sarcoidosis*

Superior vena cava obstruction has been reported in sarcoidosis due to enlarged nodes compressing the superior vena cava [150]. There has been one report of a young woman who died with progressive pulmonary hypertension and was found to have non-caseating granulomas obliterating the pulmonary veins as well as granulomas in the hilar lymph nodes and liver [151]. The author has seen a similar patient.

### **Extrathoracic sarcoidosis**

#### **Clinical features**

##### *Lymphatic system*

The lymph nodes most frequently affected in sarcoidosis are those of the hilar and paratracheal groups. Of the superficial nodes, those of the right scalene group are most commonly affected but enlargement of any of the superficial nodes may be found. The involvement of superficial lymph nodes provides readily accessible tissue for biopsy.

##### *Eyes*

Ocular manifestations have been reported in as many as 25% of patients with sarcoidosis [32,152–155]. The eyes should be examined routinely, preferably with a slit lamp, in all cases since mild asymptomatic eye involvement may be commoner than is suspected. Uveitis is the most frequent manifestation of eye involvement causing symptoms. It develops acutely with pain in the eyes and misty vision in about one-third of patients, while the remainder show the chronic form that develops insidiously. Anterior uveitis is usual in self-limiting sarcoidosis, while posterior uveitis is typical of the chronic form of the disease. Acute conjunctivitis, sometimes of the phlyctenular type, may

occur particularly in early sarcoidosis and conjunctival biopsy may provide proof of the diagnosis. Keratoconjunctivitis sicca results in dryness of the eyes; a Sjögren-like syndrome may be encountered if the salivary glands are also involved. The lacrimal glands may also be enlarged.

### *Skin*

The most common skin manifestation in sarcoidosis is erythema nodosum, which in severe cases may be associated with prolonged fever [156]. Recurrent episodes of erythema nodosum may occur sometimes over many years [157]. Maculopapular eruptions, subcutaneous nodules, plaques and lupus pernio are other lesions that may be found. Occasionally old scars, including tattoos, may become infiltrated with sarcoid tissue (Fig. 39.12). The clinical examination of a case of suspected sarcoidosis should include inspection of previous traumatic, operation and vaccination scars for the development of lividity, which suggests infiltration. Women appear to be more prone to chronic skin lesions. Rarely the site of a previous Mantoux test may become infiltrated with sarcoid tissue.

Sarcoidosis of the upper respiratory tract carries a 50% risk of the development of lupus pernio within 2–3 years [158]. The early use of corticosteroid therapy may prevent this complication.

### *Upper respiratory tract*

Sarcoidosis of the upper respiratory tract is an uncommon but disabling manifestation of the disease affecting the nose, nasopharyngeal mucosa and the larynx [158–160]. Disease of the nasal mucosa results in crusting, obstruc-

tion and discharge in varying degrees. The septum and inferior turbinates are most commonly involved, although sometimes the lesions are more widespread. The mucosa is erythematous and granular, with associated polypoid hypertrophy causing nasal obstruction that is aggravated when stagnation and crusting leads to suppuration, purulent discharge and rarely epistaxis.

Disease of the laryngeal and pharyngeal mucosa may coexist with, or be independent of, nasal lesions. Hoarseness, cough, dysphagia and dyspnoea secondary to upper airway obstruction may occur [160]. Inspection reveals erythema and oedema with or without punctate nodules and mass lesions.

A patient presenting with sarcoidosis of the upper respiratory tract has a 50% chance of developing lupus pernio, although one feature may be present without the other. Sarcoidosis of the upper respiratory tract and lupus pernio are nearly six times more common in women in the child-bearing years of life. Both are indicators of chronic fibrotic sarcoidosis, developing insidiously and progressing indolently over the years with associated chronic lesions of the lungs, skin or bone.

Nasal septal or palatal perforations may complicate untreated sarcoidosis of the upper respiratory tract. Misguided submucous resection in this condition almost certainly results in septal perforation. The Kveim test is almost always positive, and this assists in the differential diagnosis of granulomas in the upper respiratory tract, which includes Wegener's granulomatosis, tuberculosis and leprosy.

### *Alimentary system*

Involvement of the salivary glands and liver is common, while affection of the pancreas and gastrointestinal tract is

**Fig. 39.12** Subcutaneous nodules and infiltration of biopsy scar with sarcoid tissue in a Black patient.

rare. Pancreatitis has been reported [161,162], and bloody ascites secondary to granulomatous involvement of the peritoneum has been described in two cases [163]. There is no evidence that Crohn's disease is a manifestation of sarcoidosis and the Kveim test has been shown to be negative in such cases [164–168]. Liver involvement, though frequent as judged by the results of biopsy, does not usually cause symptoms unless there is gross enlargement, when discomfort may occur.

#### *Uveoparotid fever*

Uveoparotid fever was first described by Heerfordt in 1909 [12] as a febrile illness characterized by uveitis and swelling of the parotids, accompanied frequently by facial palsy. At first thought to be a mild form of tuberculosis, it is now recognized as one of the curious combinations of organ involvement that can occur in sarcoidosis. Parotid enlargement is bilateral in more than half the cases and may be mistaken for mumps [169]. Unlike mumps, however, the swollen parotids are not painful (Fig. 39.13). Enlargement of the lacrimal and other salivary glands may sometimes accompany the uveoparotid syndrome.

#### *Haemopoietic system*

Enlargement of the spleen is relatively common in sarcoidosis and is usually symptomless, although gross enlargement may give rise to abdominal discomfort. Spontaneous rupture of the spleen has been recorded [170]. Hypersplenism is rare but, like haemolytic anaemia, has been described [170,171].

**Fig. 39.13** Enlarged parotid glands as a presenting feature in sarcoidosis.

#### *Nervous and endocrine systems*

Sarcoidosis affecting the nervous system by infiltration or sarcoid deposits may result in a variety of clinical pictures [172–190]:

- 1 peripheral neuropathy or mononeuritis multiplex;
- 2 cranial neuropathy, most commonly of the seventh cranial nerve (sarcoidosis is the commonest cause of bilateral facial nerve palsy);
- 3 lymphocytic meningitis, in which the cerebrospinal fluid shows pleocytosis, increased protein and decreased glucose levels;
- 4 meningoencephalitis;
- 5 space-occupying lesions;
- 6 epilepsy;
- 7 brainstem and spinal syndromes are rare but may masquerade as multiple sclerosis, amyotrophic lateral sclerosis or spinal tumour.

Left recurrent laryngeal nerve palsy due to compression of the nerve by enlarged mediastinal nodes has been reported as the presenting symptom of sarcoidosis [189,190].

In most series, the majority of patients have presented with the neurological abnormalities; in only a minority did neurological signs develop in patients with an established diagnosis of sarcoidosis. The reported series illustrate the infinite variety of the clinical expression of central nervous system (CNS) sarcoidosis (and the difficulty in making the diagnosis in the absence of evidence of sarcoidosis in other systems), the chronicity of this form of the disease in most instances, and its variable and often poor prognosis even when corticosteroid therapy is employed [177,191,192].

The affinity of sarcoid granulomas for cerebral vessels has been stressed by many authors and may offer one explanation for the variable response to corticosteroid therapy. Areas of cerebral ischaemia and infarction have been described in relation to granulomatous angiitis. The development of meningeal fibrosis is another feature that may determine progression of neurological phenomena and limit response to corticosteroid therapy and may sometimes compel surgical intervention for relief of hydrocephalus or intractable epilepsy.

Sarcoid invasion of the posterior pituitary or hypothalamus may result in diabetes insipidus. It is rare for sarcoidosis to involve the anterior pituitary or other endocrine glands sufficiently to disturb function. Hypothalamic hypothyroidism has been described and it is important to be aware of this possible complication of CNS sarcoidosis because of the therapeutic implications [173]. In addition to diabetes insipidus and hypopituitarism, hypothalamic involvement can result in other diverse manifestations, including marked somnolence, hypothermia, personality changes, central alveolar hypoventilation, loss of libido, amenorrhoea and cessation

of normal sexual development. These hypothalamic syndromes have been reviewed extensively [193–195].

### *Musculoskeletal system*

Bone involvement in sarcoidosis most commonly affects the terminal phalanges of the hands and feet, although the proximal limb bones are occasionally involved in severe cases. Radiologically, the punched-out bone cysts initially noted by Kriebich [9] and later studied in detail by Jungling [15] are the most typical of the skeletal changes, although diffuse infiltration of the phalangeal shaft and destruction of cortical and medullary bone are occasionally seen. It is not uncommon for a single digit to be wholly spared while others on the same hand or foot are severely involved. The bone lesions are not affected by treatment with corticosteroids [196]. They were present in only 3% of the Edinburgh series [26].

Subcutaneous tissue swellings affecting several of the fingers or toes are frequently associated with bone involvement and add to the disability resulting from progressive disorganization of the terminal phalanges. It is unusual to find radiographic bone changes without clinical evidence of abnormality in the digits. Unlike the bone lesions, the subcutaneous swellings are usually improved by corticosteroid therapy. Skin sarcoids commonly coexist.

In one series of 29 patients with sarcoidosis of bone observed for up to 43 years, the hands and/or feet were affected in 26 patients, the nasal bone in three and in one each the hard palate and temporal bones were involved [197]. There were three types of bone lesion: lytic in 25 patients, permeative in nine and destructive in three. Lytic lesions are minute defects of the cortex, or larger defects of both cortex and medulla, and are usually rounded. With the passage of time, the larger defects may form the characteristic appearances of cysts. Permeative lesions show 'tunnelling' of the cortex of the shaft of the phalanx, leading to distortion of the normal cortical and trabecular pattern, which is replaced by a fine or coarse reticular pattern. Destructive lesions are rapidly progressive, with multiple fractures of devitalized cortex, sequestrum formation and local deformity. In this series, soft tissue swelling preceded the radiographic abnormality for up to 4 years in 10 patients, accompanied it twice, followed it once and was absent in 16 (55%). Bone involvement was usually an incidental finding when sarcoidosis presented elsewhere. Other features included intrathoracic sarcoid (86%), lupus pernio (48%), skin plaques (41%), ocular lesions (48%), nasal mucosal disease (24%), hepatomegaly (13%), splenomegaly (10%) and parotid enlargement (10%). Pulmonary infiltration with or without lymphadenopathy was present in three-fifths and hilar adenopathy alone in one-third of patients. Abnormalities in the chest radiographs of patients with bone sarcoid resolved in only 20%, underlining the chronicity of the sarcoid process in these patients.

Sarcoid granulomas may occur in skeletal muscle, most commonly affecting the pectoral, shoulder, arm and calf muscles [198–204]. The muscle foci are usually symptomless, but exceptionally there may be pain, weakness, atrophy or even pseudohypertrophy [205]. Only very rarely can nodules be palpated in muscles; they can be more often detected in tendon sheaths. Respiratory muscle weakness due to sarcoid involvement has been reported [206,207]. Serum creatine phosphokinase may be elevated [208].

Sarcoid arthritis independent of erythema nodosum has been described [209]. In the vast majority of cases, however, the polyarthralgia of sarcoidosis is simply a feature of the erythema nodosum syndrome.

### *Genitourinary system*

Sarcoidosis may affect the kidneys in two ways, both of which can cause varying degrees of functional impairment [210–213]. There may be either invasion of the organ by sarcoid granulomas or deposition of calcium in and around the renal tubules (nephrocalcinosis) secondary to hypercalcaemia or, more commonly, hypercalciuria [214]. The reported incidence of hypercalcaemia has varied greatly. One large series found persistent hypercalcaemia in only 8 of 364 patients (2.2%) and only in association with severe and widespread sarcoidosis [215]. The disturbance in calcium metabolism in sarcoidosis is due to an unexplained increase in sensitivity to vitamin D, which results in increased absorption of calcium from the gut. The value of corticosteroid drugs in reversing this effect is well established; they are thought to act by accelerating the already delayed clearance of 1,25-dihydroxyvitamin D<sub>3</sub> from the blood [216]. It has been shown that exposure to sunlight increases the degree of hypercalcaemia, and there is an impression that hypercalcaemia in sarcoidosis is commoner in sunny climes [217]. The symptoms include tiredness, muscular weakness, thirst, polyuria, vomiting and constipation. There may be deposition of calcium in the kidneys, cornea and subcutaneous tissues [217]. When direct sarcoid involvement of the kidney is suspected renal biopsy is justified [218].

Renal calculi are a rare but not unknown presenting feature of sarcoidosis; in an Italian series 1% of patients presented with renal calculi [219]. Glomerulonephritis may also rarely occur in sarcoidosis [220]. Sarcoidosis of the epididymis has been reported [221].

### *Cardiovascular system*

The cardiovascular system may be affected by sarcoidosis in two ways. Extensive pulmonary fibrosis can lead to cor pulmonale, while actual involvement of the myocardium may result in dysrhythmias, conduction disorders, heart failure or sudden death [222–225]. Pericarditis has been recorded [224,226]. ECG abnormality in the absence of

cardiac symptoms is a frequent finding during the course of sarcoidosis [227,228].

There is good reason for believing that involvement of the heart in sarcoidosis is more frequent than was once thought [226]. A clinicopathological study of 84 unselected patients demonstrated myocardial involvement in 25% [229]. Most often only a small part of the myocardium is involved, explaining the absence of clinical features. Occasionally angina may result from granulomatous myocardial disease [230,231]. In a UK series of 163 patients with cardiac involvement, 70 had died at an average age of 47 years [224]; 45 deaths were sudden and in 26 of these sarcoidosis was previously undiagnosed. Other principal manifestations were ventricular extrasystoles or tachycardia in 64, complete heart block in 31, lesser heart block in 56, supraventricular tachycardia in 35 and myocardial disease in 34. If suspected, a 24-h ECG, echocardiogram, exercise ECG and thallium imaging should be performed and treatment with corticosteroids and antiarrhythmics initiated for any significant dysrhythmia [224,225]. Cyclophosphamide therapy may be effective in steroid-unresponsive disease [232]. Combined heart and lung transplantation is the ultimate effective therapy [233] for life-threatening cardiac sarcoidosis and lives may be saved in the waiting period by employing implantable pacemakers or automatic cardiac defibrillators [234]. Endomyocardial biopsy has been successfully used to establish the diagnosis [235].

## Investigations

### Pulmonary function tests

There have been numerous studies of abnormalities of pulmonary function associated with the various stages of intrathoracic sarcoidosis [236–243]. Functional impairment cannot be predicted from the radiographic appearances [242]. A patient whose chest film has become normal may still have significant pulmonary sarcoidosis as judged by reduction in static lung volumes, decreased pulmonary compliance and a reduction in carbon monoxide diffusing capacity [243]. Conversely, extensive shadowing may sometimes be associated with little impairment of function. The most subtle indication of lung function abnormality appears to be a decrease in *DLCO*, which may only be evident on exercise studies. Reduced *DLCO* has been demonstrated in patients whose radiograph only shows hilar adenopathy.

Evidence of airflow obstruction is common in patients with sarcoidosis; two separate studies of black North American and British white patients found airflow obstruction in over 60% [244], indicating that this is the commonest physiological abnormality in pulmonary sarcoidosis. Airflow obstruction was found at all stages of disease, was unrelated to smoking history and was not reversible with bronchodilators [244,245]. It seems likely

that this finding reflects the common occurrence of airway involvement in sarcoidosis [246] and is consistent with the presence of bronchial hyperreactivity [142,247].

Abnormal oxygen uptake responses to exercise in patients with mild pulmonary sarcoidosis have been reported and have been attributed to possible subclinical impairment of right-sided cardiac function [248].

### Kveim test

It is now well established that particulate saline suspensions of sarcoid tissue contain, in varying amounts, some component that when injected intradermally in a patient with active sarcoidosis can provoke the slow development of an epithelioid cell granuloma of sarcoid type. This is the basis of the Kveim test [249–252] and for over two decades a steady accumulation of data has resulted in a wide acceptance of the test as a reliable and clinically useful aid to diagnosis. Unfortunately, shortage of suitable tissue and fears of transmission of viral infection have caused the test to be abandoned in most centres.

### Value of the test

False-positive reactions are rare, only 1–2% [168,249], and a positive test can be regarded as virtual proof of active sarcoidosis. The more active the disease, the greater the likelihood of the test being positive. Its highly specific nature makes it an invaluable tool in the elucidation of atypical cases and often obviates the need for more traumatic forms of biopsy. Unfortunately, even with the best test substances presently available, positive results are obtained in only 75% of patients with clinical evidence of the disease [32,253].

### Nature of the test substance

Sarcoid tissue suitable for preparation of Kveim test substance must meet the following criteria [254]:

- 1 it must have a sufficiently high concentration of the active principle;
- 2 it must have a sufficiently low concentration of substances giving non-specific, inflammatory responses;
- 3 it must be free from agents of transmissible disease;
- 4 there must be sufficient tissue to provide adequate supplies to prove these points and to be available for general diagnostic use.

The details of the preparation of Kveim test substance are of prime importance in relation to both the activity and specificity of the material; monitoring of bulk test material for activity and specificity should be a continuous process [166,255,256]. Douglas and colleagues [250] have described in detail a technique used in Edinburgh for the preparation of two test suspensions that have satisfied all the criteria when subjected to worldwide validation.

The Kveim test substance is remarkably stable; its activity is only destroyed by autoclaving or exposure to alkali. It can stand boiling for 30 min [257]. Freeze-dried test material kept for several months at room temperature retains its potency and specificity [253,258]. The active principle is particulate [259]. It is not water soluble and is not contained in the nucleoprotein or the lipid fraction of the material [260,261], and its precise nature is still unknown. Similar skin reactions can be induced in patients with sarcoidosis by the injection of non-viable autologous BAL cell preparations [262]. Other substances can produce local sarcoid reactions in systemic sarcoidosis (e.g. killed tubercle bacilli) but none so reliably as sarcoid tissue.

Studies with subcellular fractions (nuclear, mitochondrial, microsomal and submicrosomal) prepared by homogenization and differential ultracentrifugation have shown that results equal to those of the whole homogenate can be obtained by all fractions except the submicrosomal. These results tend to support the view that the active principle in sarcoid tissue that evokes the epithelioid granulomatous response is of particle form and is concentrated in the membrane-containing elements [250,251].

#### Method of testing

The test is performed by injecting intradermally 0.1–0.2 mL of a suspension of human sarcoid tissue, usually obtained from a cervical gland. Rarely, splenectomy for splenomegaly due to sarcoidosis allows the preparation of large quantities of test substance. Within 2–3 weeks a positive test shows a purplish-red nodule at the site of injection. Biopsy at 4–6 weeks reveals sarcoid tissue on histological examination (Fig. 39.14).

The forearm is usually used as the site of injection but, for cosmetic reasons, the upper and outer thigh may be used in females. Biopsy is made with a Hayes–Martin drill, which can remove a small core of skin without leaving a significant scar.

Coincident corticosteroid therapy depresses the reaction and, if at all possible, treatment should not be given until the test is read.

#### Nature of the Kveim reaction

The epithelioid granuloma of the Kveim reaction shares the histological, histochemical, immunofluorescent and ultrastructural features of the granuloma found within affected organs in sarcoidosis, and it has been supposed that the substances and mechanisms involved in the development of both granulomas are the same [249,252,263]. Two theories, which are not mutually exclusive, have been proposed. On the one hand, some believe that the Kveim test detects a specific aetiological agent, some component of which is present in the sarcoid tissue from which the test substance is made. Others have felt that it simply demonstrates a specific form of tissue reactivity common to sarcoid patients. Despite the increasing sophistication of immunological studies, it is still not known which of these two theories, if either, is correct. Siltzbach has supported the unitarian concept of sarcoidosis, using as evidence the fact that the spleen of a single sarcoid patient has provided a test substance that has been shown to produce specific reactions in sarcoid patients all over the world, suggesting that 'a primary inciting agent may be at work' [254]. The uniformity of response to Kveim testing in all geographical areas has been taken to support the concept of a single disease rather than a syn-

**Fig. 39.14** Kveim biopsy showing typical sarcoid granuloma.

drome, and a single aetiology rather than a multiple one. It might equally mean that the test is detecting a specific form of reactivity. The Kveim 'reaction' remains an immunological puzzle [252].

### Tissue biopsy procedures

Tissue biopsy is often crucial to the diagnosis of sarcoidosis. Strictly speaking, an absolute diagnosis of sarcoidosis cannot be made on suggestive clinical and radiographic findings alone because of the similarity between sarcoidosis and other conditions such as tuberculosis and reticulosis. Similarly, a biopsy report describing sarcoid tissue is of itself insufficient for absolute diagnosis since this might simply represent a local sarcoid tissue reaction. When typical clinical and radiographic findings are supported by histological proof of the sarcoid granulomatous process and tuberculosis has been excluded by the tuberculin test and by bacteriology, the diagnosis of sarcoidosis can be confidently made.

The desirability of histological confirmation of the disease in every case was undoubted in the years when the patterns of disease were being evaluated. However, we have now reached the stage when the quest for demonstrable sarcoid tissue must be tempered by the knowledge concerning the presentation and behaviour of sarcoidosis that has accrued over the last three decades. In the UK, a young woman with erythema nodosum, bilateral hilar lymphadenopathy and a negative tuberculin test has sarcoidosis for all practical purposes and physicians would hesitate to employ any biopsy procedure in these circumstances. On the other hand, obscure bilateral pulmonary changes may justify biopsy, including scalene node biopsy, mediastinoscopy or preferably transbronchial lung biopsy via the fiberoptic bronchoscope. If potent Kveim reagent is not available, the decision whether to perform diagnostic biopsy exercises the physician's judgement.

The tissues found to be useful for biopsy in sarcoidosis have increased in number with the years (Table 39.5) and now include superficial lymph nodes, mediastinal glands, skin, palate, bronchus, lung, liver, conjunctiva, gastrocnemius muscle, bone marrow and old scars with evidence of infiltration. The wide range of positivity for scalene fat-pad biopsy is probably explained by failure to distinguish between biopsy of palpable nodes and 'blind' biopsy.

Transbronchial biopsy of lung and bronchial wall via the flexible fiberoptic bronchoscope is the procedure of choice in the diagnosis of diffuse pulmonary abnormality of probable sarcoid aetiology and is employed especially if there are cogent reasons for securing a diagnosis earlier than can be expected from the Kveim test [264,265]. A minimum of four lung biopsies by this method optimizes the chances of securing a diagnosis.

**Table 39.5** Results of biopsy in sarcoidosis (several authors). Figures in parentheses indicate percentage positive.

### Tuberculin testing

Numerous studies have shown that about two-thirds of patients with active sarcoidosis fail to react to 100 TU; about one-quarter react to 100 TU, less than one-tenth to 10 TU and less than 1 in 20 to 1 TU.

### Serum angiotensin-converting enzyme

Lieberman was the first to report that serum angiotensin-converting enzyme (ACE) was elevated in patients with sarcoidosis compared with controls, giving rise to the hope of a relatively simple method for confirming the diagnosis [266]. Serum ACE has been reported to be elevated in 75% of patients with active sarcoidosis, with higher levels in Blacks than whites [267]. The enzyme probably originates from active epithelioid and giant cells and is elevated in BAL fluid of patients with active sarcoidosis compared with that of controls and patients with inactive sarcoidosis [268–270]. Serum ACE may be elevated in conditions other than sarcoidosis, such as Gaucher's disease, leprosy and atypical mycobacterial infection [267]. In other conditions, the combined false-positive rate for non-sarcoid patients has been reported to be as high as 20% in one series [271].

A number of studies have reported falls in serum ACE levels following steroid therapy and also in association with clinical improvement in the natural course of the disease [267,272–275]. Nevertheless, clinical or radiographic deterioration may occur without an associated

rise in serum ACE, and clinical or radiographic improvement may occur without any fall in elevated serum ACE levels [274–276].

In summary, there is evidence that serum ACE is elevated in a majority of patients with sarcoidosis and that its measurement may therefore be of value in substantiating a diagnosis in a difficult case. Elevated serum ACE is neither sensitive nor specific for sarcoidosis. Serial measurements do not necessarily predict activity of disease or outcome as assessed clinically, radiographically or in terms of respiratory function and are therefore unnecessary in routine clinical management, although possibly of interest in research studies [274].

### **Gallium-67 scanning**

Gallium-67 is concentrated in metabolically and mitotically active tissues, where it binds to granulocytes and macrophages [110,277]. Sarcoid and other inflammatory tissue avidly accumulate gallium and gallium scanning may be used to delineate it. Following an intravenous injection of  $11 \times 10^7$  Bq of gallium-67 citrate, simultaneous anterior and posterior scans of the thorax are performed 3 days later [278]. The pattern of uptake is generally diffuse and involved nodes may be well defined. In one study, 65% of patients with sarcoidosis had increased uptake of gallium-67 with little correlation between degree of uptake and clinical, physiological and radiographic findings [279]. Close correlations between gallium uptake and the total number of lymphocytes, or T lymphocytes recovered by BAL and serum ACE levels, have been reported [279,280]. Gallium uptake diminishes with spontaneous or steroid-induced improvement in sarcoidosis but, as with serum ACE, abnormal values may be found even in the presence of a normal chest film and pulmonary function [273,274,279]; positivity of the initial gallium scan appeared to have no predictive value for outcome in one prospective study [274].

In summary, increased gallium-67 uptake by the lungs is found in the majority of patients with pulmonary sarcoidosis but is not specific for this condition. It is an expensive investigation involving a substantial radiation dose to the patient and cannot at present be justified in the routine investigation of this disease. A possible role in the diagnosis of atypical cases of sarcoidosis has been suggested [281] but awaits further evaluation.

### **Bronchoalveolar lavage**

As already mentioned, BAL fluid from patients with pulmonary sarcoidosis contains increased numbers of T lymphocytes, with a high ratio of CD4 to CD8 T cells, and increased macrophages in comparison with control fluid. This finding may be used to support but not prove a diagnosis of sarcoidosis [90,98]. The first 20 mL of the BAL

specimen should be discarded and cell counts made on subsequent specimens [282,283].

### **Measurements in blood, urine and sputum**

Serum calcium should be measured as well as 24-h urinary calcium. Serum globulins may be elevated, although this finding is of little diagnostic or prognostic significance. Routine examination of the peripheral blood is of no value in diagnosis. If sputum production is a feature, acid-fast bacilli should be sought by direct smear or culture.

### **CT of the thorax**

CT of the thorax is usually unnecessary in sarcoidosis. It may be of value, when used with contrast, in differentiating hilar enlargement due to lymphadenopathy from enlargement of the pulmonary vessels. Hilar and mediastinal lymphadenopathy are usually found to be more extensive than the plain chest radiograph indicates. Pulmonary abnormalities may include irregular linear opacities, ground-glass shadowing (particularly related to bronchovascular bundles, interlobar septa and in subpleural areas) and nodular or ill-defined shadows with a similar distribution. CT is frequently abnormal in the presence of apparently normal lungs on the chest radiograph [284–286].

### **Strategy for investigation of suspected sarcoidosis**

As already mentioned, where bilateral hilar lymphadenopathy and erythema nodosum occur together in a tuberculin-negative young woman it is probably excessive to pursue a tissue diagnosis. However, in the case of obscure pulmonary infiltrates where sarcoid is suspected, initial investigations should include a baseline measurement of lung volumes and *DLco* and tuberculin testing. If corticosteroid therapy is not obviously imminently indicated, a Kveim test may establish the diagnosis within 6 weeks. If early therapeutic intervention seems likely to be necessary or if Kveim test reagent is unavailable, the diagnosis is most likely to be established at fiberoptic bronchoscopy, when at least four transbronchial lung biopsies (with or without endobronchial mucosal biopsies) should be taken to search for epithelioid granulomas. Serum and 24-h urinary calcium should be measured.

The role of BAL has been investigated in two careful studies. Keogh and colleagues [287] reported 19 patients with pulmonary sarcoidosis, of whom 80% were initially classified as having 'low-intensity alveolitis' (BAL T cells <28% of total and/or gallium scan negative) and 20% as having 'high-intensity alveolitis' (BAL T cells >28% of total and gallium scan positive). Clinical, radiological and physiological assessment did not predict the intensity of

the alveolitis. With serial assessments of these parameters they showed that 75% of patients with high-intensity alveolitis reverted to low-intensity alveolitis spontaneously, whereas the reverse phenomenon occurred in 12% of patients with low-intensity alveolitis. An episode of high-intensity alveolitis was associated with deterioration in pulmonary function in 87%. They suggested that staging the intensity of alveolitis in these patients might aid therapeutic decision-making. Turner-Warwick and colleagues [274] have repeatedly staged 32 patients with gallium scans, BAL and serum ACE while withholding the information from the clinicians who managed the individual patients on the basis of clinical, radiological and functional parameters. Initial values for gallium uptake, BAL lymphocyte count and serum ACE were not predictive of the outcome in individual patients. Although these parameters tended to normalize with clinical improvement in disease, poor concordance with clinical, radiological and functional parameters was observed. This would suggest that in the routine investigation of pulmonary sarcoidosis, measurement of serum ACE, gallium uptake and BAL lymphocyte count are of little help in planning the future management of the patient.

In extrapulmonary sarcoidosis, attention should be directed to obtaining biopsy material from the most accessible involved site (see Table 39.5).

## Treatment

In nearly every case, corticosteroid therapy can suppress the manifestations of active sarcoidosis, a possible exception being CNS sarcoidosis. Although there is considerable debate about the indications for corticosteroid therapy in thoracic sarcoidosis, most are agreed that steroid therapy is indicated when vital organs are involved or if there are significant symptoms.

### Thoracic sarcoidosis

Bilateral hilar lymphadenopathy alone is not an indication for corticosteroid therapy since the vast majority resolve spontaneously with the passage of time. The associated arthralgia may necessitate treatment with non-steroidal anti-inflammatory drugs; exceptionally, when systemic upset is severe with persisting or recurring erythema nodosum, a few weeks of corticosteroid therapy may be required to suppress symptoms.

There is no universal agreement about the indications for corticosteroid therapy in stage II and stage III thoracic sarcoidosis [288]. One extreme view would be that in a disease which may have a mortality of 5–10% and significant disability due to fibrosis in 3–20% if left untreated [288], it is mandatory to treat all patients with pulmonary shadowing due to sarcoidosis. At the other extreme, it can be argued that corticosteroids are unnecessary in the man-

agement of stage II and III sarcoidosis since controlled trials show that although there may be early (e.g. at 6 months) significant differences in chest radiography or lung function in the treated versus the control group, in the longer term (1–15 years) there are no significant differences between the treated and control groups [289–295]. By the nature of their design, however, these trials of necessity exclude patients for whom corticosteroid therapy was considered clinically indicated and the patients studied therefore presumably had a relatively good prognosis. There is no doubt that if all patients with stage II and stage III sarcoidosis were treated with corticosteroids many would be unnecessarily exposed to the risk of side-effects.

Our own policy is to treat patients with significant symptomatology, most commonly dyspnoea. In asymptomatic patients, baseline assessment of lung volumes and DLCO is undertaken and the patient then observed with repeated radiographic and functional assessment at regular intervals for 6–12 months. Treatment may be initiated if significant symptoms develop, if there is significant radiographic or functional deterioration or if at the end of the observation period there has been no significant improvement. There is evidence to suggest that serial assessment of gallium uptake, serum ACE or BAL lymphocyte counts does not contribute any additional advantage to such a management plan [273]. A recent report from the USA of the management of 98 patients endorses the view that the use of simple clinical criteria augmented by simple radiographic and pulmonary function tests minimizes the number of patients exposed to corticosteroid therapy and results in no adverse outcomes [296]. Treatment, when required, is initiated with prednisolone 20–40 mg in daily or alternate-day regimens and is continued for 3–6 months, when a slow and graduated reduction in dosage may be attempted while clinical, radiographic and functional status is monitored. If relapse is to occur, it is commonly seen when the prednisolone dose is reduced below 7.5–15 mg; this necessitates a return to a higher dose and a further period (6–12 months) on a continuing maintenance dose, commonly 10 mg daily, before further reduction in dosage is attempted. In the Edinburgh series, corticosteroid therapy was given to 260 patients; this was discontinued in 80% in 2 years and their follow-up was uneventful [137]. This experience contrasts with that found in a predominantly black American population where relapses occurred in the majority on reduction of prednisolone dosage below 10–15 mg and the majority required more than 2 years of treatment, perhaps reflecting the greater severity and chronicity of the disease in this population [297]. Although most patients respond satisfactorily to the dosage regimen outlined above, individual relatively unresponsive patients may require higher doses of prednisolone initially to suppress activity, and a small proportion of patients are found to require

long-term treatment with corticosteroids. Despite this, some progress remorselessly to chronic pulmonary fibrosis.

Anecdotal experiences and accounts, including our own, of the benefits of high-dose inhaled corticosteroids in the management of pulmonary sarcoidosis, often in patients who reject systemic corticosteroid therapy, are beginning to be addressed by controlled trials [298]. At present the precise role of this intervention in replacing, or reducing the dose of, systemic corticosteroids remains to be determined [299,300].

There has been a report of successful treatment of pulmonary sarcoidosis with cyclosporin in three patients, two of whom were unresponsive to steroids and one in whom corticosteroids were contraindicated [301]. Cyclosporin was a logical choice since it acts by suppressing T-helper lymphocytes and there may be a case for further studies of its use in different clinical situations. Chlorambucil has

also been used successfully in corticosteroid-resistant sarcoidosis [302].

### Extrathoracic sarcoidosis

Treatment with the same dosage schedule of oral corticosteroids is also indicated in the management of eye involvement uncontrolled by topical steroids and in persistent hypercalcaemia or hypercalciuria to prevent the development of nephrocalcinosis and renal failure. CNS, symptomatic muscle and myocardial sarcoidosis are all indications for corticosteroid therapy, although CNS sarcoidosis may be unresponsive even to high doses of prednisolone. In one such case of unresponsive sarcoid meningitis, improvement was recorded following whole brain irradiation [303]. Disfiguring skin lesions may justify treatment, as may parotid and lacrimal gland enlargement and symptomatic splenic involvement.

# PULMONARY LYMPHOCYTIC ANGIITIS AND GRANULOMATOSIS

ANTHONY SEATON

A number of conditions, originally grouped together because they share the common factors of a lymphocytic angiitis or vasculitis with a tendency to granuloma formation, may cause disease of the respiratory tract [1–9]. It is now recognized that despite their similar histological appearances they differ in clinical characteristics, natural history and aetiology, and several represent low-grade lymphocytic neoplasms. Nevertheless, their names have become familiar to chest physicians and since they all cause similar diagnostic problems they are considered together in this chapter. These conditions are:

- 1 classical Wegener's granulomatosis;
- 2 limited Wegener's granulomatosis;
- 3 midline granuloma;
- 4 lymphomatoid granulomatosis;
- 5 benign lymphocytic angiitis and granulomatosis;
- 6 necrotizing sarcoid granulomatosis;
- 7 bronchocentric granulomatosis.

Two other conditions characterized by eosinophilic granulomas, polyarteritis nodosa and allergic granulomatosis (Churg–Strauss syndrome), have been considered separately in Chapter 38.

## Classical Wegener's granulomatosis

In 1931 Klinger [10] described a patient with destructive sinusitis, nephritis and disseminated vasculitis but it was not until 1936 that Wegener [11] clearly defined the triad as a distinct clinical and pathological entity. In 1954 a review by Godman and Churg [12] led to the establishment of firm criteria for the diagnosis. Classical generalized Wegener's granulomatosis is characterized by (i) necrotizing granulomas in the respiratory tract, (ii) generalized focal necrotizing vasculitis and (iii) focal necrotizing glomerulonephritis. In practical terms the demonstration of one or more of these in combination with positive serological evidence is now generally accepted as fulfilling the criteria. When one element of the triad is absent it is usually the renal or the upper respiratory tract component.

## Frequency

Wegener's granulomatosis is more common than was once thought. Up to 1967 approximately 200 cases had been reported, although two series published in the 1980s matched this total number of cases [13–15]. Since then, the description of the antineutrophil cytoplasmic autoantibody as a marker of the disease, and the attention drawn to it at the International Symposium at the Mayo Clinic in 1986, have increased the rate at which it has been diagnosed, and it is now estimated to occur at a rate of about 5–12 new cases per million population per annum [16].

There is a slight male preponderance (male/female ratio 3:2) and most patients reported have been of Caucasian extraction. The condition may be found at any age including childhood, although the peak incidence is in the fourth and fifth decades [15,17]. There is a suggestion that, at least in England, the disease may present more frequently in the winter months [16].

## Pathogenesis and antineutrophil cytoplasmic antibodies

The pathogenesis of Wegener's granulomatosis remains unclear. The finding of a significant increase in HLA-DR2 frequencies suggests that in some cases there may be a genetic predisposition to this disease [18], and the increased incidence in winter is consistent with Wegener's original hypothesis that infection may play an aetiological role. There are indications that deposition of circulating immune complexes in vessel walls initiates the vasculitis. The antibodies are usually of the IgG or IgM class. Following deposition, the immune complexes trigger the complement cascade thus generating potent chemotactic factors for polymorphonuclear leucocytes such as C5a [19]. Once attracted to the site, neutrophils release lysosomal enzymes, such as elastase and collagenase, with resultant necrosis of vessel walls [20]. In support of this concept is the finding of circulating immune complexes in patients

with Wegener's granulomatosis, their correlation with disease activity or relapse and the probable beneficial therapeutic effect of plasmapheresis [13,21–25]. In addition IgG, IgM and complement deposition have been demonstrated in tissue from kidney, lung and the maxillary sinus of patients with Wegener's granulomatosis [23,24,26]. However, the failure to demonstrate deposition of immunoglobulins and complement in involved tissue [26–28] or the presence of circulating immune complexes in all patients [13] suggests that the phenomenon may be relatively transient or, alternatively, that the immune complex concept of pathogenesis may not be the whole story [29].

There is also evidence that cellular as well as humoral immune mechanisms play a part in pathogenesis. Immune complexes can cause granuloma formation [30]. Lymphocytes, mainly T cells, and monocytes are seen infiltrating vessels [27]. In addition, it is suggested that T lymphocytes can be sensitized to antigen and on contact with it release lymphokines, resulting in cellular infiltration, giant cell formation and tissue destruction [9]. After ingestion of immune complexes, macrophages may also release tissue-damaging lysosomal enzymes or transform into epithelioid cells and form granulomas.

In 1985 van der Woude and colleagues reported an association between Wegener's granulomatosis and the presence in the blood of antineutrophil cytoplasm antibodies (ANCA), and this finding has been replicated by a number of other investigators [31–33]. ANCA react with cytoplasmic granules in neutrophils and demonstrate one of two staining patterns: diffusely cytoplasmic (cANCA) or per-

inuclear (pANCA) (Fig. 40.1). The main target of cANCA appears to be proteinase C and that of pANCA myeloperoxidase [34,35]. Initial use of ANCA in an indirect immunofluorescence test suggested that they had a very high specificity and sensitivity for the diagnosis of Wegener's granulomatosis, based on studies from large specialized units. However, ANCA have been shown to occur in other diseases, including such common conditions as tuberculosis, lung cancer and human immunodeficiency virus (HIV) infection, and a recent audit of the results of the use of the test in a regional diagnostic service has shown a sensitivity of 65% and a specificity of 77% in patients with respiratory symptoms, cANCA being somewhat more sensitive [36]. False-positive results were found in other autoimmune diseases, cancer, pulmonary emboli and pulmonary fibroses. Since Wegener's granulomatosis is relatively rare, the positive predictive value of the test is quite low, at around 45%.

The role, if any, of ANCA in pathogenesis remains the subject of speculation, and it is debated whether they are a cause or consequence of some of the pathological features. In support of a pathogenic role, ANCA have been shown to cause neutrophils to release free radicals and to injure endothelial cells, while T lymphocytes have been demonstrated to become sensitized to ANCA [37–39]. It has been proposed on the basis of *in vitro* studies that viral or other illnesses that lead to the release of cytokines, such as tumour necrosis factor, cause neutrophil enzymes to migrate to the surface of the cell from the primary granule and that presentation of these antigens at the cell surface leads to the development of the ANCA [37]. This in turn

**Fig. 40.1** Neutrophil leucocytes from a patient with Wegener's granulomatosis stained by immunofluorescent technique to show cytoplasmic antibodies.

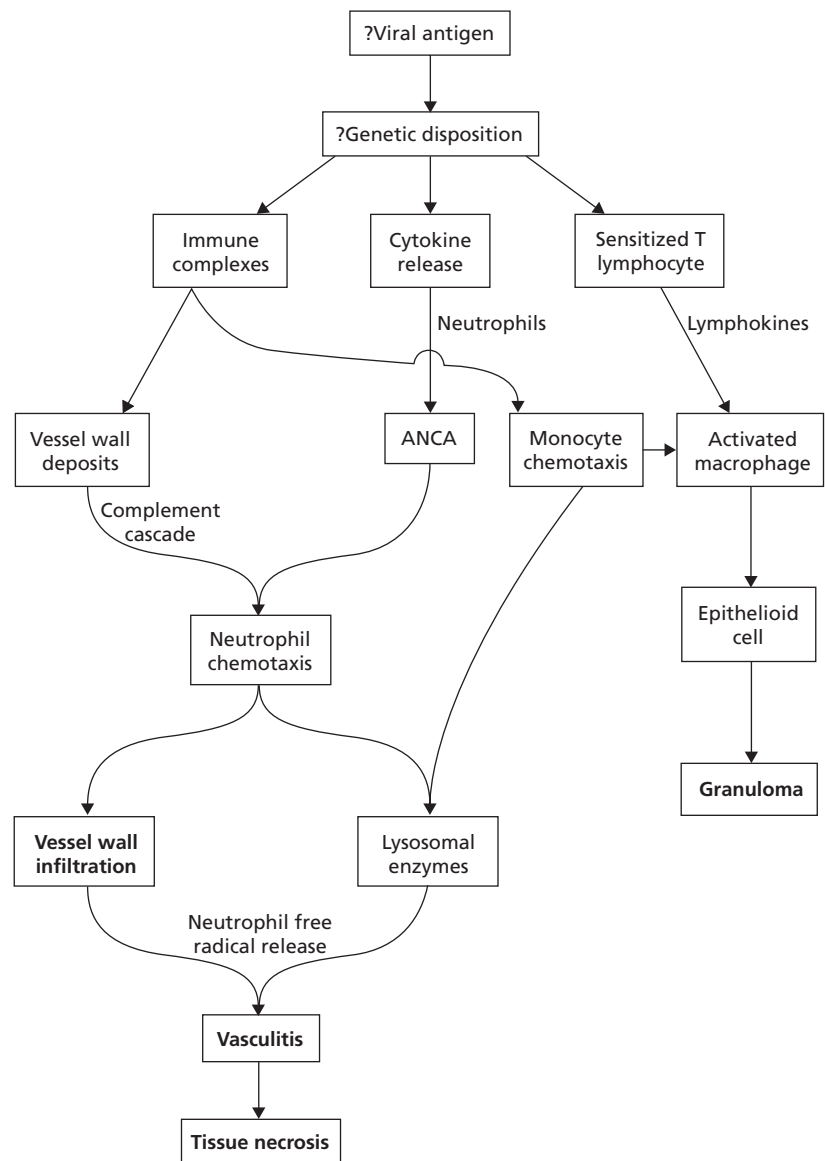

may cause release of free radicals, damage vascular endothelium and recruit more neutrophils. On balance it seems likely that a condition characterized by granulomatous inflammation of lungs, nasal passages and kidneys is likely to have an environmental cause, the pathological changes being a consequence of inflammation resulting from secondary disturbances of the immune defences. This is in keeping with Wegener's original suggestion that the disease is an altered response to an infective organism. An outline of a proposed pathogenesis is shown in Fig. 40.2 [9].

### Pathology

The pulmonary lesions are characterized by the presence of confluent or isolated areas of basophilic necrosis that frequently display cavities or crevices [40,41]. Communi-

cation with a sizeable bronchus may occur, resulting in evacuation of the necrotic material. The lesion may look distinctly suppurative, resembling an abscess or a septic infarct. Eosinophils are present throughout the lesion and are more numerous within the necrotic core where destructive angiitis of muscular arteries and veins can be seen (Fig. 40.3). The tissue around the foci of necrosis consists of fibroblastic and histiocytic proliferation with variable numbers of giant cells (Fig. 40.4). Scanty lymphocytes and plasma cells are also seen in the tissue surrounding the necrotic areas. Similar pathology may be seen in other affected organs.

The renal lesion is a focal necrotizing glomerulonephritis [26,28]. Fibrinoid necrosis with destruction of one or more glomerular capillary loops, along with a neutrophil infiltrate, is characteristic. Granulomatous change may be seen around affected glomeruli, as may necrotizing

**Fig. 40.2** Proposed pathogenesis of Wegener's granulomatosis. (Adapted from Leavitt & Fauci [9].)

**Fig. 40.3** Lung biopsy from Wegener's lesion stained for elastic tissue showing destruction and loss of elastic laminae and partial obliteration of lumen in artery adjacent to area of necrosis (elastic van Gieson  $\times 35$ )

(a)

(b)

(b) Higher-power view of same lesion showing poorly formed granuloma with giant cells and chronic inflammatory cells (haematoxylin & eosin  $\times 110$ )

vasculitis of small and medium-sized vessels. When healing occurs following treatment, the changes seen are hyalinization of affected areas, capsular adhesions and epithelial crescent formation in Bowman's capsule. With suitable immunofluorescent stains it is often possible to demonstrate immunoglobulin or complement deposition in the glomerular capillary membrane and/or mesangium.

### Clinical features

The clinical expressions of Wegener's granulomatosis are diverse and the patient may present initially to practitioners from almost any branch of medicine [42,43]. Neither sex predominates. The course varies from a very acute systemic illness with dramatic pulmonary and renal manifestations to a much more chronic, often nasal, inflammatory condition, although acute presentations are more usual. Chronic courses are more frequent in those without renal involvement. In the large National Institutes of Health (NIH) series, most patients at presentation had evidence of upper airways involvement and fewer than half had lung involvement, although this developed in almost all eventually. Renal disease at presentation was relatively uncommon but developed in almost 80% within 2 years; similarly, eye involvement increased from 15 to 50% over the same period [43]. The main nasal symptoms are rhinorrhoea, nasal mucosal ulceration or sinusitis. To these may be added respiratory symptoms such as cough and haemoptysis. Alternative presentations are with systemic symptoms, such as anorexia, malaise, fever, weight loss and arthralgia, or with involvement of other organs such as the skin, eye or ear. When the diagnosis is suspected haematuria and proteinuria should always be sought as evidence of renal involvement. The most common systems involved are discussed below.

### Upper respiratory tract

Nasopharyngeal lesions can include mucosal ulceration with crusting, perforation of the nasal septum and varying degrees of sinusitis. In chronic cases, saddle nose deformity may occur but erosion of skin or palate as seen in midline granuloma does not [15]. 'Strawberry gums' or hyperplastic gingivae that are red to purple in colour with many petechiae may be seen [44,45]. Radiographs of the nasal sinuses may show obliteration due to chronic bacterial infection, resulting in sinus wall thickening and new bone formation [46]. Biopsies usually show either acute or chronic inflammation, with granulomas or vasculitis in only 50% of cases [15].

### Lower respiratory tract

Respiratory tract symptoms may lead to the finding of an abnormal chest film [47]. The most common finding is of

solitary or multiple nodules 1–10 cm or more in diameter and these may cavitate (Fig. 40.5). Rarely, rupture of a cavitated nodule may result in pneumothorax; even more rarely a cavitated nodule may be colonized by an aspergilloma [48–50]. The radiological appearances are very variable [47,51]. Nodular and alveolar infiltrates are commonly seen on chest radiographs and may appear relatively insignificant. Such findings should not lull one into a false sense of security if other clinical features are present to suggest the diagnosis. Alveolar infiltrates may be due to intrapulmonary haemorrhage, which is more common than was once thought and may be detected by increases in diffusing capacity for carbon monoxide [52,53]. Small pleural effusions may occur. Endobronchial involvement is not uncommon and may result in large airway stenosis or lobar collapse [54,55]. CT may be helpful in providing evidence of vascular involvement, showing vessels leading into nodules and small peripheral densities suggestive of microinfarcts [56].

Functionally, patients with Wegener's granulomatosis frequently have decreased lung volumes and diffusing capacity, although airways obstruction is even more common and presumably reflects endobronchial disease [57]. The defects in pulmonary function improve with therapy but a persistent decrease in diffusing capacity is often found.

### Urogenital

There may be no renal tract manifestations at the time of presentation. More commonly, microscopic or macroscopic haematuria with proteinuria is found. If renal failure is not established at presentation, it may develop rapidly and progressively and is the principal reason for seeking an urgent pathological diagnosis and initiating chemotherapy as soon as possible. Renal failure carries a poor prognosis but, even when established, recovery is possible with present-day therapy [25,58–60]. Other, uncommon urogenital manifestations include involvement of prostate, testes, ureter and penis [61].

### Eyes

Eye manifestations are found eventually in some 60% of patients [15,43], including corneal/scleral ulceration, granulomatous keratitis or uveitis, conjunctivitis, proptosis, orbital pseudotumour, dry eyes, retinal vein occlusion and retinal artery thrombosis [62,63].

### Ears

The ear is also involved in about 60% of patients [15]. The patient may present with serous or purulent otitis media, usually secondary to nasopharyngeal ulceration and obstruction of the eustachian tube [64,65]. The middle ear

**Fig. 40.5** Chest films of patient acutely ill with Wegener's granulomatosis: (a) cavities in consolidation in right mid zone and consolidation at left base; (b) tomography of one of the lesions just after commencement of treatment showing its nodular structure; (c) residual fibrosis after 1 month of prednisolone and cyclophosphamide.

and mastoid may be destroyed by granulomatous tissue, with associated lesions of cranial nerves, most commonly the fifth, seventh, ninth and twelfth [65,66]. Sensorineural hearing loss may occur due to cochlear inflammation [65].

### Skin

Skin and mucosal involvement occurs in up to 50% of cases [15]. In one review of 75 patients with dermatological manifestations, the most frequent findings were palpable purpura and oral ulcers, with skin nodules, skin

ulcers and necrotic papules occurring less commonly [67]. Other manifestations included gum hyperplasia, pustules, digital necrosis and livedo reticularis. In general the purpuric lesions were associated with vasculitic histopathology and the non-purpuric with granulomas.

### Joints

Polyarthralgia is common and is seen in about 50% of cases [15]. In most series, true arthritis has been less common, although it was present in the majority of

patients in one report, presumably representing selection bias [68].

### Heart

Cardiac disease as a presenting manifestation of Wegener's granulomatosis must be very rare indeed, although subtle cardiac involvement in established cases is probably less so. The most frequent manifestations are pericarditis, myocarditis and dysrhythmias due to coronary vasculitis [15,69,70]. Aortitis and aortic valvulitis with sterile endocarditis have been reported [70,71]. The availability of ANCA allows the diagnosis to be made more readily than previously and the condition should be considered in cardiac disease of obscure aetiology.

### Nervous system

Central nervous system involvement can occur with direct invasion by granulomatous tissue from ear or sinus, with resultant cranial nerve involvement. Remote granulomatous involvement of the brain is also recognized [72]. Vasculitic lesions of the peripheral nervous system may give rise to mononeuritis multiplex, while central nervous system vasculitis may result in thrombosis or haemorrhage in brain tissue.

### Gastrointestinal system

Gastrointestinal involvement is not common but patients have been described presenting with features more typical of inflammatory bowel disease, and severe haemorrhage has been recorded in patients with vasculitis of bowel [73–75].

### Investigations

Most patients have a normochromic, normocytic anaemia with a raised erythrocyte sedimentation rate, leucocytosis and hyperglobulinaemia. Plasma levels of C-reactive protein are raised and, although not specific for this disease, have been used as an index of activity [76]. As discussed above, a positive test for ANCA, especially those of the diffuse type (cANCA), in conjunction with consistent clinical features is as close as there is to a diagnostic test [31,77] (see Fig. 40.1).

### Differential diagnosis

Where the clinical findings are suggestive, no time should be wasted before obtaining biopsies of the involved organs, most commonly the upper respiratory tract and the lungs. Renal biopsy should be considered even in the absence of renal manifestations, since early renal disease may be detected and confirm the diagnosis.

The differential diagnosis is wide-ranging and includes conditions as diverse as polychondritis and Behçet's disease. Other vasculitic diseases may need to be considered, such as polyarteritis, systemic lupus erythematosus and Churg–Strauss syndrome, other granulomatous diseases such as sarcoidosis and the infectious granulomatoses and neoplastic diseases such as nasopharyngeal lymphoma or pulmonary Hodgkin's disease. Finally, the other principal pulmonary–renal condition, Goodpasture's syndrome, frequently enters into the differential diagnosis. In children, diagnostic confusion with Henoch–Schönlein purpura has been recorded [17].

### Treatment

The management of the condition may be tailored to the presenting clinical course. It has to be said that as the condition is rare, guidance on treatment at present is based on the results of case series rather than on controlled trials, and these are largely (and almost inevitably) derived from highly specialized centres where selection bias ensures that the case mix is atypical. There is therefore an important need for exercising good clinical judgement in interpreting the literature in relation to one's individual patient. Having said this, there is no real dispute about the management of ill patients with progressive lung or renal disease, who require to be treated vigorously with corticosteroids and cyclophosphamide in high dose in order to induce remission. The problem of how to treat arises mainly in those less ill patients in whom the course is slowly progressive and the diagnosis made early, the disease being primarily granulomatous and confined to lungs and upper airways. In such patients, co-trimoxazole may be effective in a dose of 960 mg twice daily [78,79]. If this does not bring about improvement within 6–8 weeks, prednisolone 40 mg on alternate days should be added, reserving the further addition of cyclophosphamide 2 mg/kg daily for those who still fail to respond [77].

In most cases the presentation warrants treatment with corticosteroids and cyclophosphamide. The NIH group originally reported 93% complete remission in 85 patients using an induction regimen of cyclophosphamide 2 mg/kg and prednisolone 1 mg/kg [15]. More recently they have reported improvement in 91% and complete remission in 75% of 180 patients, mostly treated with the same regimen though including some less severely affected patients treated with cyclophosphamide, other cytotoxic drugs or steroids alone or in combination [43]. However, 50% of remitting patients suffered relapse, although half of all remissions lasted at least 5 years. There was a 13% mortality, either from the disease itself or from side-effects of treatment, and almost all patients suffered some side-effects. Even after a 10-year remission, some 20% of patients relapse.

The usual starting dose of prednisolone of 1 mg/kg daily may be increased in severely ill patients. Once complete remission has been achieved, usually within about 4 weeks, the prednisolone is changed to an alternate-day regimen; if remission is maintained, the prednisolone is tapered to zero over about 1 year depending on the clinical response. Cyclophosphamide is usually started at 2 mg/kg daily or more in severe cases and continued for a year after complete remission has been achieved, when a slow but graduated reduction in dosage (25 mg every 2–3 months) can be made to zero if no relapse occurs. If relapse occurs, therapy has to be restarted or increased. Cyclophosphamide causes serious side-effects; cystitis occurred in 43% of the NIH series, bladder cancer in 3% and myelodysplasia in 2%. The dose may have to be reduced to ensure a leucocyte count of greater than  $3 \times 10^9/L$ , with a neutrophil count of  $1 \times 10^9/L$ . Other side-effects of cyclophosphamide include hair-thinning, an increased incidence of herpes zoster, gonadal dysfunction and rarely, but significantly, the later development of leukaemia or lymphoma [80–83]. The side-effects of the steroids are as expected and include a much increased risk of infections, though this can be reduced by alternate-day therapy.

The major challenge in treating Wegener's granulomatosis relates to prevention and management of side-effects. If these are unacceptable, therapy with methotrexate may be effective [84]. Azathioprine has also proved successful in occasional cases [85], but neither of these drugs has become established as first-line treatment. Other experimental therapies have included plasmapheresis and transfusion of pooled gamma globulin [22,25,76,86–88]. If renal failure develops, dialysis and even renal transplantation may be necessary [15].

There has been much discussion of the value of serial ANCA titres in monitoring response and detecting early relapse. There is a general relationship between level of antibodies, severity of disease and risk of relapse, and concentrations fall with successful treatment. However, the finding of high or rising ANCA in a patient on treatment is not a sure indication that relapse is imminent and should probably only be taken as a guide to more careful follow-up rather than as an indication for increasing the therapy [89,90]. As always, good clinical judgement should be used in a patient on treatment who shows rising ANCA, in balancing the risks of increasing the dose against those of side-effects; the patient's clinical status should generally be the main determinant of change in therapy.

Finally, the occasional mechanical complication may persist in large airways despite standard treatment. Such endobronchial obstruction has been shown to respond to radiotherapy and bougienage or to stenting [55,91].

## Prognosis

The condition, when recognized, was uniformly fatal prior to the introduction of corticosteroids; these drugs alone made little long-term difference, with a mean survival of 5 months and 90% of patients dead within 2 years [92]. Better recognition of the condition allows diagnosis in a relatively benign category with a much better prognosis than that of the more common progressive disease, though one suspects that many of these, treated initially with co-trimoxazole, relapse later. Of those requiring standard cyclophosphamide and corticosteroid treatment, more than 80% can be expected to be alive at 5 years [43,93]. However, as noted above, there is a large cost in terms of therapeutic side-effects, including late development of lymphomas and bladder cancer. The patient is probably never free of the risk of relapse, even when complete and prolonged remission appears to have occurred, and life-long outpatient supervision is advisable [85].

## Limited Wegener's granulomatosis

In 1966 Carrington and Liebow identified a group of 16 patients with otherwise typical Wegener's granulomatosis in whom renal disease was not present [94–96]. A positive ANCA test is less frequent than in the classical form of the disease. There may be involvement of other tissues such as the skin and eye [1,62,63]. The pulmonary lesions in this condition predominate in the lower lobes and the most common form is a discrete lesion greater than 1 cm in diameter. In two-thirds of cases the lesions are multiple and bilateral and in one-third cavitation occurs.

The patients usually present with lower respiratory tract symptoms with variable degrees of systemic upset, although a lesion may be discovered at routine radiographic examination of an asymptomatic patient. The disease appears to follow a less aggressive course than classical Wegener's granulomatosis, although relapse after treatment is not infrequent and may be in a more aggressive form with renal involvement [85]. A 20% 5-year mortality was reported prior to modern treatment [95]. Death has occurred from progressive involvement of the lung or massive haemorrhage from a cavitating lesion but is more likely now as a result of relapse to a more aggressive form.

This condition responds to steroids and should be treated with both cyclophosphamide or azathioprine and corticosteroids as for the classical form of the disease [1].

## Midline granuloma (nasal T-cell lymphoma)

Midline granuloma is a localized process characterized by

a pansinusitis and destructive lesions of the nasal septum and soft and hard palate. The process is localized to the upper airway, although ulceration can occur through skin [97]. If left untreated, death eventually ensues from cachexia, haemorrhage, meningitis or infection [98]. Biopsies of involved tissue reveal acute and chronic inflammation with necrosis and it is unusual to see granulomas or vasculitis [99,100]. There is no associated systemic disease. It must be differentiated from Wegener's granulomatosis, nasal carcinoma and infectious diseases [100]. Recent evidence indicates that it is a locally invasive lymphoma of T-cell variety [101,102]. There are interesting geographical variations in its incidence and it is more common in the Orient. In many cases, Epstein-Barr virus has been demonstrated in the malignant T lymphocytes and may be causative [103-105]. Radiation therapy has proved successful in arresting the process, although management should be discussed with appropriate lymphoma specialists if possible [87,98,100].

## Lymphomatoid granulomatosis

### Pathology

Histologically, lymphomatoid granulomatosis is a necrotizing angiocentric and angiodestructive infiltrative process composed of small lymphocytes, plasma cells, histiocytes and atypical lymphoreticular cells. It predominantly involves the lungs, although infiltration of skin, kidney and the nervous system is not uncommon [1,106]. Upper airway lesions are unusual [106]. Recent evidence suggests that the pulmonary manifestation of this condition, in contrast to cutaneous and head and neck manifestations, may be predominantly an Epstein-Barr virus-associated B-cell lymphoma with a marked T-cell reaction leading to the vasculitis [107]. However, this hypothesis is based on study of small numbers of cases and it would not be surprising if other series showed different results in the future.

### Clinical features

In a study of 152 patients there was a male/female ratio of 1.7:1 [106]. Most patients present with chest and/or systemic symptoms such as fever or malaise. Neurological signs, including peripheral neuropathy, are not uncommon. Laboratory investigations are generally unhelpful. The chest film shows a similar frequency and distribution of nodular masses, cavitation and migratory lesions as are seen in Wegener's granulomatosis [108]. However, reticulonodular changes are seen in lymphomatoid granulomatosis and not in Wegener's granulomatosis. A skin rash, most commonly raised and erythematous, and neurological signs are the most common extrapulmonary findings and renal involvement may occur.

### Treatment and prognosis

The median survival of the 152 patients in the original series of Katzenstein and colleagues [106] was 14 months and 94% were dead by 3 years; 12% of all patients developed generalized evidence of lymphoma. The outcome appeared to be independent of any therapy employed, including steroid and cytotoxic drugs. Before the lymphomatous nature of the condition was recognized there were reports of response of localized disease to radiotherapy [109], and in one study 7 of 15 patients achieved complete remission for a mean of 5.2 years with cyclophosphamide 2mg/kg and prednisolone 1mg/kg [110]. Current advice would be to regard the condition as a low-grade lymphoma *ab initio* and treat it accordingly, bearing in mind the toxic effects of antineoplastic drugs and the relatively benign course of low-grade lymphomas [111].

## Benign lymphocytic angiitis and granulomatosis

### Pathology

This very rare clinical entity is characterized by pulmonary infiltrates consisting of lymphocytes, plasma cells and histiocytes, with lymphocytic infiltration of arteries and veins [41,112,113]. Compression or infiltration of the walls of the bronchioles that resembles bronchiolitis obliterans is commonly seen. The chest radiographic appearances are most frequently of a single nodule but may show other features similar to Wegener's granulomatosis. It is now regarded as a T-cell lymphoproliferative disease but is probably not a malignant lymphoma [114].

### Clinical features

The condition may present with symptoms suggesting respiratory tract infection or be discovered incidentally on routine chest radiography. It is one of the lung conditions that may appear in HIV infection [115]. Extrapulmonary involvement is uncommon but skin and eye lesions have been reported.

### Treatment and prognosis

It is frequent for the lung lesions to wax and wane and for opacities to clear spontaneously with minimal residual fibrosis, only to be followed by the development of fresh lesions elsewhere. Development into lymphomatoid granulomatosis has been described [5]. Corticosteroid therapy is ineffective, although cytotoxic drugs, particularly chlorambucil, have been reported to be effective in producing remission [40,41].

**Fig. 40.6** Lung biopsy from patient with necrotizing sarcoid granulomatosis showing irregular necrosis to the right of a zone of confluent epithelioid granulomas (haematoxylin & eosin  $\times 120$ ).

## Necrotizing sarcoid granulomatosis

### Pathology

First described by Liebow in 1973 [1], this condition is characterized by pulmonary lesions with granulomatous vasculitis and pneumonitis against a background of sarcoid-like granulomas and parenchymal necrosis of variable extent (Fig. 40.6). Muscular pulmonary arteries and veins are infiltrated by histiocytes, spindled mononuclear cells, lymphocytes and giant cells, with a tendency towards marked involvement of the subintima [116,117].

### Clinical features

The disease is three to five times more common in women than men and the average age at presentation is 50 years. Patients may be entirely asymptomatic or may present with chest pain, cough or dyspnoea with or without systemic features such as malaise, fever, night sweats, weight loss and lethargy [116–119]. Extrapulmonary involvement is unusual but granulomatous disease of the nervous system has been described.

The chest film most commonly shows bilateral nodules or nodular infiltrates, although solitary nodules have been seen (Fig. 40.7). Miliary shadowing, hilar lymphadenopathy and pleural effusions have been recorded.

### Treatment and prognosis

The condition may resolve spontaneously [116] though in most cases resolution has been achieved either with corticosteroid therapy or surgical resection of a single lesion. It remains possible that this pathological entity is simply a variant of sarcoidosis since there are many immunological parallels [5,120]. The author has reviewed one case that

progressed to a fatal conclusion, with widespread pulmonary arteritis and pulmonary hypertension, owing to a foolish medicolegal misdiagnosis of asbestosis.

## Bronchocentric granulomatosis

### Pathology

The characteristic feature of bronchocentric granulomatosis is a necrotizing granulomatous reaction centred around airways (Fig. 40.8). Large and small airways are involved but the most marked changes are in the periphery, where irregular necrotic lesions lie within collapsed consolidated lung tissue. The necrotic lesions consist of airways with ulceration of the surface epithelium and cellular debris within the lumen, often with irregular masses of eosinophils. Occasional true epithelioid granulomas are present in the tissues surrounding the necrotic lesions. There is a variable but often marked peribronchial inflammatory infiltrate in which eosinophils may be prominent. Proximal bronchi may show plugging by inspissated material and there may be chondritis and cartilage destruction within their walls. Pulmonary arteritis is not a major feature and when it occurs is secondary to the bronchial and parenchymal infiltration [1,121,122].

### Clinical features

Patients with bronchocentric granulomatosis divide into two groups: those with and those without asthma [121,123]. The asthmatic patients present with chest-related symptoms such as cough, haemoptysis, dyspnoea, wheeze and chest pain, whereas the non-asthmatics tend to present with non-specific symptoms such as malaise, fever or fatigue.

(a)

(b)

**Fig. 40.7** Chest films of patient with necrotizing sarcoid granulomatosis: (a) nodular lesions in right lung, originally thought to be metastases; (b) 2 weeks later, showing increasing consolidation also at right base.

The radiological appearance is commonly that of a solitary mass lesion, most often in the upper lobe, although alveolar and reticulonodular infiltrates have also been described [124]. Adenopathy and cavitation are uncom-

mon. Asthmatic patients tend to be younger and have peripheral blood eosinophilia, positive skin tests, and precipitins and elevated IgE levels to *Aspergillus fumigatus*. This organism may be present in sputum or lung biopsy

**Fig. 40.8** Section of lung resected from patient with bronchocentric granulomatosis. Small bronchi are seen with walls partly destroyed by a florid infiltrate with lymphocytes and eosinophils and intraluminal cellular and granular debris (haematoxylin & eosin  $\times 85$ ).

specimens [121,122], and pathological appearances of bronchocentric granulomatosis are frequently present in lung specimens resected from patients with typical bronchopulmonary aspergillosis [125]. The asthmatics have an eosinophil pulmonary infiltrate, whereas the non-asthmatics have a predominance of neutrophils. It has been postulated that the main requirement for the development of bronchocentric granulomatosis is a sustained inflammatory insult within the lumen, often associated with proximal bronchial obstruction and distension of distal airways by retained secretions and cellular debris [122]. In the asthmatic, the allergic response to *Aspergillus* (or other fungus) provides the insult [121]. In the non-asthmatics the insult is usually unidentified though inter-

esting case reports of bronchocentric granulomatosis in association with tuberculosis, echinococcosis, ankylosing spondylitis and seropositive arthritis suggest that it may be varied [126–130].

### Treatment and prognosis

Most patients with this disease are diagnosed after thoracotomy and resection of the diseased lung effects a cure; some patients require corticosteroids for some time post-operatively [121,123,131]. For those with residual or recurrent disease, corticosteroid therapy is recommended with an initial dosage of 40 mg of prednisolone daily, tapering once remission is achieved.

# LUNG CANCER

RONALD J. FERGUSON

## Epidemiology

### Size of the problem

During the twentieth century lung cancer has emerged as the most common form of malignant disease in the western world. In the UK after the Second World War there was a dramatic rise in the numbers of patients dying from lung cancer (Fig. 41.1) and for some time it has been the most common cause of cancer death in men. Around 40 000 new patients are now seen each year, accounting for more than 8% of all male deaths and 4% of all female deaths [1]. In the European Community, almost 160 000 new patients are registered each year as having lung cancer and in 1992 the Surgeon General reported 133 700 deaths from the disease in the USA [2].

The disease is more common in men than women, although this difference has become smaller; in the USA and the UK, the male/female ratio was approximately 5:1 in 1970 but fell to around 2.5:1 in 1982 [3]. Recently, mortality rates have been falling in men of all ages. In contrast, lung cancer is the most rapidly increasing cause of cancer death in women. Since 1984, deaths from lung cancer have exceeded those due to breast cancer among women in Scotland and in some parts of northern England, and lung cancer looks set to be the major cancer killer of women in other areas. Encouragingly, mortality rates have recently begun to decline in younger women in England and Wales (Fig. 41.1), although the incidence of the disease continues to climb in the older age groups.

### Aetiological factors

#### Tobacco smoking

It has been known for many years that the smoking of tobacco cigarettes is by far the most common cause of lung cancer [4,5]. In England, Wales and the USA, it is estimated that 92–94% of lung cancer deaths are attributable to tobacco smoking in males, the figures in females being

78–80% [6]. The evidence for this association is derived from epidemiological studies, the earliest of which were retrospective. Doll and Hill [7] compared over 1300 lung cancer patients in hospital with a matched group of controls. It was found that there were very few non-smokers in the cancer group and this group contained many more heavy smokers than were found in the control group. Further support for the hypothesis that smoking causes lung cancer was provided by prospective studies. Doll and Peto [8] correlated the smoking habits of over 34 000 British doctors with lung cancer mortality over a period of 20 years and found a significant decline in both cigarette smoking and lung cancer mortality in this group. This was in contrast to the general male population in whom neither mortality rate from the disease nor tobacco consumption fell. These data were subsequently supported by studies of a large group of American physicians [9] and of British women doctors [10].

It has been estimated that cigarette smokers are 8–20 times more likely to develop lung cancer than lifelong non-smokers and that the extent of this risk correlates closely with the number of cigarettes smoked [11]. There is some evidence to suggest that the risk of lung cancer may be reduced by the use of filter tips and by lower tar yields [6,12]. Following cessation of smoking, the risk of developing carcinoma of the lung has been shown to decline progressively with time. However, even by 10–20 years the risk is still about 2.5 times that of non-smokers [13].

Unfortunately, smokers do not only increase their own risk of developing lung cancer, since there is evidence that the inhalation of other people's tobacco smoke (passive smoking) on a long-term basis is linked with an increased incidence of the disease. This risk was first noted in a study of non-smoking wives of heavy smokers in Japan [14]. It has now been shown that people who have been exposed to environmental tobacco smoke in their homes, both as children and adults, have an increased risk of lung cancer [15].

Pipe and cigar smokers have a slightly reduced risk of developing lung cancer compared with cigarette smokers,

**Fig. 41.1** Mortality from lung cancer by age and year of death, England and Wales 1921–90: (a) males, (b) females. (From Lung and Asthma Information Agency Factsheet 93/1, with permission of Professor Ross Anderson.)

probably because less smoke is inhaled [13]. It is also clear that of the principal histological types of lung cancer, squamous cell carcinoma and small-cell carcinoma have the clearest association with cigarette smoking, while adenocarcinoma is the commonest histological type in non-smokers who develop the disease [6].

#### Trends in smoking and lung cancer

In the UK, the consumption of cigarettes by men rose steadily throughout the first half of this century: the average annual consumption of cigarettes per man in 1905 was 800, rising to 4420 by 1945 [16]. Since then, and particularly in the last 20 years, consumption has fallen, reaching 2380 by 1985. The pattern of annual consumption in women has lagged behind that of men, starting with 13 in 1921, reaching 1250 in 1945 and peaking at 2630 in 1974. Since then consumption has fallen, but more slowly than that of men, reaching 1930 in 1985. The prevalence of cigarette smoking shows a similar trend, decreasing from 52% of men in 1972 to 31% in 1990; prevalence among women has fallen from 41% to 29% over the same time span [17]. If the current trends in the UK continue, smoking will soon be more common in women than in men. The clear link between tobacco consumption and lung cancer means that trends in the disease closely follow changes in cigarette consumption but with a lag period of approximately 20 years. Two important statistics concerning cigarette smoking will be reflected in the future pattern of lung cancer cases: (i) smoking problems among young women have increased in recent years; and (ii) most cigarette smokers are now in the less affluent socioeconomic groups in society [2]. At present the risk of an unskilled working

**Table 41.1** World age-standardized rates per 100 000 (WASR) for selected cancer registries, cancer of the trachea, bronchus and lung (ICD-9 162), 1983–87.

Japan, Osaka	41.5	Spain, Zaragoza	3.6
India, Bangalore	10.1	India, Bangalore	1.9

man dying of lung cancer is three times that of a professional man and it is likely that smoking habits are the major contributor to this difference. Table 41.1 shows the marked geographical variation in lung cancer mortality in different developed countries. The precise reasons for this variation are unclear; although socioeconomic, genetic and cultural differences exist, cigarette consumption must be important. While cigarette consumption is decreasing in all industrial societies it is extremely worrying that smoking is increasing in less developed countries, especially Africa and South America. Of the 10 nations with the highest smoking rates among males, eight are regarded as developing countries and of the top 30 only nine are industrialized [18]. If the current trends in tobacco consumption continue, it has been estimated that by the year 2025 80% of the projected 3.5 million cases of lung cancer per year will be in developing countries.

### Atmospheric pollution

The role of environmental air pollution in the production of lung cancer is controversial and has certainly been far less important than the part played by cigarette smoking. Studies carried out to investigate the effect of environmental pollution and which have allowed for tobacco consumption show that urban dwellers have a risk of lung cancer that is 1.26–2.33 times greater than people living in the countryside [19,20]. Atmospheric pollution has also been used to explain the differences of incidence in lung cancer between two countries with similar cigarette consumption (Table 41.1). Recently there has been a lot of interest in the influence of residential radon exposure in the development of lung cancer. It is known that underground miners exposed to high levels of the radon progeny that decay from uranium have an increased risk of lung cancer [21]. Residential radon is the principal source of exposure to ionizing radiation in most countries. Studies from Sweden have suggested that residential exposure to radon is an important factor in the development of lung cancer in the general population, the interaction between radon exposure and smoking being almost a multiplicative effect [22,23].

### Occupational factors

Certain occupations are associated with a higher than expected incidence of lung cancer. Table 41.2 lists a number of known causative agents and it is predictable that the list will grow with the ever-increasing complexity of industrial processes. In many instances the carcinogenic effect of the individual exposure is added to or multiplied by the effect of cigarette smoking, making the apportion-

ment of blame difficult in individual cases. Asbestos is particularly notable for its association with lung cancer. There is often a considerable latent period between exposure to asbestos and the onset of lung cancer. The risk rises until at least 30 years after first exposure, with an approximately linear relationship between the dose of asbestos and mortality and no detectable threshold dose below which there is no increased risk of lung cancer. The interaction between asbestos exposure and smoking appears important [24], all longitudinal studies having shown that the interaction between these two risk factors is close to multiplicative [25].

The precise importance of asbestos exposure in the development of lung cancer in the general population is unknown. De Vos Irvine and colleagues [26] estimated that 5.7% of cases of lung cancer in the west of Scotland were asbestos-related. Extrapolating these figures to the whole of the UK would suggest that in excess of 2000 cases a year may be related to asbestos; however, this projection may not be appropriate since the west of Scotland has been an area with classically high exposures in shipyards and construction. Data from the SWORD surveillance scheme [27] suggest that comparatively few such cases are recognized, possibly because once the patient is identified as a tobacco smoker the physician does not enquire further into asbestos exposure. Also this exposure may appear trivial and have occurred many years before the presentation with lung cancer. Other aspects of asbestos-related disease are discussed in Chapters 43 and 54.

The increased risk of lung cancer described in workers extracting metal ores from deep mines is thought to be caused mostly by radioactivity rather than the metal being mined. This radioactivity emanates from radon gas, high concentrations of which can build up in poorly ventilated mines. Groups of workers in whom lung cancer has been described include uranium miners in various American states [28], fluorspar miners in Canada [29], iron ore miners in Sweden [30] and tin miners in Cornwall, England [31]. Other occupational exposures associated with lung cancer include nickel [32], the extraction and production of chromium salts [33], the use of arsenicals in the metal refining and chemical industries [34], the use of chloroethers in production of ion exchange resins [35] and coke oven work in the steel industry [36]. It is suspected that printing ink used in the newspaper industry may have been associated with lung cancer [37].

### Pulmonary scarring

There have been reports of lung cancer occurring in close spatial relation to localized areas of pulmonary scarring and in patients with more diffuse lung fibrosis. The pathogenesis of these small numbers of 'scar cancers' is not established and in many cases the subject's tobacco smoking history may be highly relevant. This is particu-

**Table 41.2** Occupational causes of lung cancer.

Cause	Occupation
Asbestos	Mining, processing, usage
Radioactivity (radon daughters)	Metal ore mining Uranium mining Fluorspar mining

Mustard gas	Manufacture
Volatile coal products (?)	Coke oven workers
Printing ink (?)	Printing industry

larly true in patients with asbestos exposure, as mentioned above. It used to be believed that lung cancer only occurred in asbestos-exposed individuals secondary to the lung fibrosis of asbestosis, and in the UK and several other countries compensation for asbestos-related disease recognized lung cancer as work-related only if there was radiological or pathological evidence of lung fibrosis [38,39]. However, Wilkinson and colleagues [40] studied the occupational histories of 271 patients with lung cancer and a suitable control group and showed that the risk of lung cancer from asbestos exposure was independent of radiologically apparent pulmonary fibrosis.

Cryptogenic fibrosing alveolitis (see Chapter 31) is also associated with cancer of the lung and, like asbestosis, an increased incidence of adenocarcinoma has also been noted in this group [26,41]. The incidence of lung cancer has also been found to be three times higher than anticipated in over 3500 patients with sarcoidosis [42]. It is not clear whether this was due to pulmonary fibrosis, although the histological distribution was no different from that in the general population upper lobe fibrosis due to tuberculosis may be associated with neoplastic change [43], adenocarcinoma being the usual cell type. A high proportion of cases of bronchioloalveolar carcinoma (a subtype of adenocarcinoma) occurs in areas of scarring [44] and this cell type has also been described in relation to congenital cystic lung disease [45].

## Laboratory studies

Lung cancer is not a single entity but a generic term applied to a heterogeneous group of epithelial lung tumours that show varying degrees of malignancy in their different rates of progression and patterns of behaviour. Current laboratory evidence suggests that lung cancer starts with a single cell capable of developing into various pathological forms, including mixed tumours (Fig. 41.2). Clinicians recognize four major groups, namely squamous carcinoma, adenocarcinoma, large-cell carcinoma and small-cell carcinoma. Because of the markedly different growth rates and response to certain treatments of small-cell carcinomas, there is a tendency for investigators to

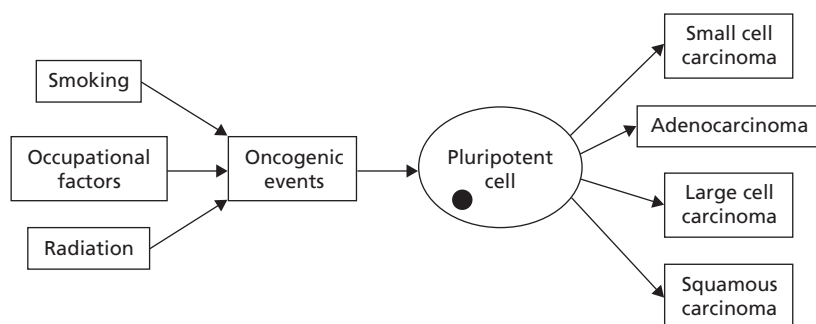

simplify even further and to apply their treatment protocols to small-cell carcinoma and non-small-cell carcinoma groups. Although this approach may be pragmatic, it has the obvious shortcomings inherent in assigning several different pathological entities to a convenient clinical category.

## Histological classification

The ideal classification of lung cancer should list histologically distinguishable groups of tumours according to clearly recognizable criteria so that different pathologists can reliably and independently arrive at the same diagnosis on the same piece of tissue. It should also be of value to physicians and surgeons who have to choose appropriate therapies and to investigators who seek to establish the value of different treatment regimens or the validity of possible aetiological links. The mere fact that several different classifications have been proposed is an indication that an ideal one has not yet been devised. The pathologist's difficulties are further increased by the now widespread submission of small quantities of biopsy material. Although the cellular characteristics of the same tumour may vary significantly in a standard section, these variations may not be detectable in a tiny fiberoptic bronchoscopy specimen or from a cytological preparation of a small number of malignant cells.

The 1981 World Health Organization (WHO) classification (Table 41.3) is still widely used [46]. Even at the time of its introduction it was criticized on the grounds that no account had been taken of differentiation and that some of the listed subtypes were of doubtful significance. It is also clear from immunoperoxidase and electron microscopic studies that lung cancers are heterogeneous in differentiation [47]. Well-differentiated squamous carcinoma may contain foci of adeno- or neuroendocrine differentiation, and tumours that are anaplastic on light microscopy may show glandular or squamous features at an ultrastructural level.

In an attempt to overcome these problems two new classifications of lung cancer have been suggested depending on the type of pathological specimen submitted. The first

**Fig. 41.2** Hypothesis for the development of different histological types of lung cancer from a single cell.

**Table 41.3** World Health Organization (1981) classification of lung tumours. Group C: malignant epithelial tumours.

1 Squamous cell carcinoma (epidermoid carcinoma) Variants: <i>spindle cell (squamous) carcinoma</i>
2 Small-cell carcinoma (a) <i>Oat cell carcinoma</i> (b) <i>Intermediate cell type</i> (c) <i>Combined oat cell carcinoma</i>
3 Adenocarcinoma (a) <i>Acinar adenocarcinoma</i> (b) <i>Papillary adenocarcinoma</i> (c) <i>Bronchioloalveolar carcinoma</i> (d) <i>Solid carcinoma with mucus formation</i>
4 Large-cell carcinoma Variants: (a) <i>Giant-cell carcinoma</i> (b) <i>Clear-cell carcinoma</i>
5 Adenosquamous carcinoma
6 Carcinoid tumour
7 Bronchial gland carcinoma (a) <i>Adenoid cystic carcinoma</i> (b) <i>Mucoepidermoid carcinoma</i> (c) <i>Others</i>
8 Others

(Table 41.4) is proposed for use with large specimens (resections or large open biopsies) [48] and is an adaptation of the pioneering work of Lamb [49]. It can be seen that the degree of differentiation is important in both squamous carcinomas and adenocarcinomas, and that tumours of neuroendocrine type are grouped together. This classification is clearly unsuitable for small biopsies. In 1993 the Lung Cancer Working Party of the UK Coordinating Committee for Cancer Research (CCCR) highlighted the problems with small specimens in a study comparing the diagnosis made on biopsy with that made on the resected specimen [50]. A diagnostic accuracy of 75% was achieved for squamous cell carcinoma, 66% for small-cell carcinoma but only 50% for adenocarcinoma. A new simplified classification (Table 41.5) was proposed that should improve the diagnostic accuracy of small biopsy specimens. The results of clinical evaluation of both these classifications are awaited.

For most pathologists, four major subgroups of lung cancer still predominate and account for about 95% of cases: squamous cell carcinoma (40–60%), small-cell carcinoma (7–25%), adenocarcinoma (10–25%) and large-cell carcinoma (5–15%) [49]. Carcinoid tumours, which account for up to 10% of cases, are discussed with other rarer tumours in Chapter 42.

### Squamous cell carcinoma

This is the most common type of lung cancer. It shows histological evidence of squamous differentiation, with

**Table 41.4** Classification of lung cancer proposed for use with large biopsy specimens. (From Edwards [48].)

Type	Tumour
1/0	Squamous carcinoma 1/1 Well differentiated 1/2 Moderately differentiated 1/3 Poorly differentiated 1/4 Undifferentiated (squamoid)
2/0	Neuroendocrine carcinoma 2/1 Carcinoid tumour 2/2 Well-differentiated neuroendocrine carcinoma 2/3 Large-cell neuroendocrine carcinoma 2/4 Small-cell carcinoma
3/0	Adenocarcinoma 3/1 Well differentiated 3/2 Moderately differentiated 3/3 Poorly differentiated 3/4 Undifferentiated
4/0	Large-cell undifferentiated carcinoma
5/0	Miscellaneous carcinomas 5/1 Tumours of mixed differentiation (i.e. adenosquamous carcinoma) 5/2 Bronchial gland carcinomas 5/3 Bronchioloalveolar carcinoma 5/4 Giant-cell carcinoma 5/5 Clear-cell carcinoma 5/6 Carcinosarcoma 5/7 Spindle cell carcinoma
6/0	Malignant epithelial tumours of uncertain type

**Table 41.5** Classification proposed by the UK CCCR Lung Cancer Working Party for routine use in the diagnosis of small biopsy specimens. (From Thomas *et al.* [50].)

Category	Tumour
1	Squamous carcinoma
2	Small-cell carcinoma
3	Adenocarcinoma
4	Non-small-cell carcinoma of specified type
5	Non-small-cell carcinoma, not otherwise specified
6	Malignant tumour, not otherwise specified
7	Technical failure
8	Carcinoma, not otherwise specified

stratification, the formation of intercellular bridges and intracellular keratinization (Fig. 41.3). The majority of squamous cell carcinomas are centrally situated, and those that are more differentiated grow more slowly and are less likely to give rise to extrathoracic metastases. Those squamous cell carcinomas that are more poorly differentiated tend to behave aggressively, extrathoracic metastases being more frequent. However, the relation-

**Fig. 41.3** Well-differentiated squamous carcinoma showing keratin pearl formation and intracellular cytoplasmic bridges (haematoxylin & eosin  $\times 305$ ).

**Fig. 41.4** Moderately differentiated adenocarcinoma showing a well-marked acinar pattern (haematoxylin & eosin  $\times 305$ ).

ship between differentiation and prognosis remains uncertain [51]. It is not uncommon for squamous cell carcinomas to cavitate.

### Adenocarcinoma

Adenocarcinomas of the lung often present a wide variety of patterns. The WHO classification, which splits tumours into acinar or papillary types, is confusing since in practice these patterns may coexist in the same tumour [52] (Fig. 41.4). Both types tend to produce mucin. There appears to be quite a wide geographical variation in the incidence of adenocarcinoma and some evidence that it is becoming more common. These tumours, unlike squamous cell varieties, are less related to cigarette smoking and are usually situated in the periphery of the lung. Often they are unrelated to bronchi other than by spread.

The WHO classification includes bronchioloalveolar carcinoma (also known as alveolar cell carcinoma) along with other adenocarcinomas. Electron microscopic studies imply that these tumours are a heterogeneous group of peripheral lung tumours that arise from any epithelial cell within or distal to the terminal bronchioles [52]. They account for about 5% of all lung cancers. Apart from their lepidic mode of spread, they behave in a similar fashion to other malignant lung tumours. On gross inspection their margins are less well defined than other members of this group, often appearing as multiple pulmonary nodules or an area of peripheral 'pneumonic consolidation'. It is common for tumour cells to exfoliate and be detected in sputum (Fig. 41.5). Regional and more distant metastases may occur less commonly than is the case with other lung tumours. At the light microscopic level these tumours as well as other adenocarcinomas may be indistinguishable

**Fig. 41.5** Bronchioloalveolar carcinoma showing tumour cells lining alveolar walls, forming papillary structures with shedding of clumps of malignant cells into alveolar spaces (haematoxylin & eosin  $\times 150$ ).

**Fig. 41.6** Undifferentiated small-cell carcinoma showing many mitoses (haematoxylin & eosin  $\times 305$ ).

from metastatic adenocarcinoma arising from an extrathoracic primary site, the most common of which are pancreas, colon, breast, stomach and kidney.

### Small-cell carcinoma

This group contains the most malignant tumours of the lung and accounts for 20–25% of cases. The WHO classification [46] divides small-cell carcinoma into three main types.

**1** Small or oat-cell carcinomas characterized by a proliferation of cells with round or oval nuclei and scanty cytoplasm (high nuclear/cytoplasmic ratio) (Fig. 41.6). These cells are about twice the size of lymphocytes, which they superficially resemble.

**2** The intermediate cell subtype, which contain cells less

regular in shape with more abundant cytoplasm. There is some evidence that this subtype containing some large cells is more resistant to chemotherapy.

**3** A combined subgroup, which includes rare examples of small-cell carcinoma containing areas of squamous carcinoma or adenocarcinoma. Probably only about 1% of tumours fall into this category [53]. It is accepted that they should be managed as small-cell carcinoma and carry the same prognosis.

Small-cell carcinomas usually arise in central bronchi. They are often grouped with carcinoid tumours as they probably originate from common neuroendocrine precursor cells. Small-cell carcinomas grow rapidly and metastasize early and widely, so that disease is rarely limited to the chest at necropsy. At presentation over two-thirds of patients have evidence of extensive disease, the most

important clinical sites of metastases being the liver, central nervous system (CNS) and bone. Other frequent sites include the abdominal lymph nodes, adrenals and other abdominal organs.

### Large-cell carcinoma

These tumours account for about 15% of lung cancers. The group is somewhat heterogeneous and many authorities now regard it as a diagnostic wastebasket [48]. The tumours tend to be anaplastic, light microscopy showing no features of maturation and the presence of large, less well-differentiated, polygonal, spindle-shaped or oval cells with abundant cytoplasm (Fig. 41.7). Electron microscopy may show features of squamous cells or adenocarcinoma. Many authors feel that they may be undifferentiated examples of squamous carcinoma or adenocarcinoma in which only anaplastic material has been sampled. It is obviously significant that the entity of large-cell carcinoma does not exist in the UK CCCR proposed classification for the pathology of small biopsy specimens [50]. The majority of large-cell carcinomas arise towards the lung periphery and are bulky. The two variant forms in the WHO classification are rare. Clear-cell carcinoma contains large rounded cells with clear cytoplasm and is commonly mistaken for metastatic renal cancer.

### Biology

The lack of progress in the treatment of lung cancer has led to a growth of interest in the biology of the disease, with the hope that an increase in knowledge could be translated into therapeutic advances. It is now possible to take tumour cells from a patient with lung cancer and grow them in the laboratory in the form of cell lines or as

xenografts in immunosuppressed animals [53,54]. These models of human lung cancer have facilitated the study of the biology of the disease. The tumours can be maintained indefinitely and remain cytologically identical to the original biopsy specimen. There are a number of areas where advances in our understanding of basic mechanisms at the cellular level may soon be translated into benefits for the patient with lung cancer.

### Growth factors

Growth factors are polypeptides that take part in the control of cell differentiation and proliferation. They act locally on tumour cells via growth factor receptors but may also be found in the circulation [55]. It has long been known that small-cell tumours are able to synthesize a wide range of peptides and hormones and that these substances can readily bind to cell receptors causing autocrine growth stimulation (Fig. 41.8). Bombesin/gastrin-releasing peptide has been shown to be an important growth factor both *in vitro* [56] and *in vivo* [57]. It has also been shown that the growth of small-cell lung cancer in the laboratory can be inhibited by a monoclonal antibody to bombesin [58]. Other important growth factors in small-cell lung cancer include vasopressin and bradykinin [59], opioids [60] and insulin-like growth factor 1. Numerous other substances have been shown to be secreted by small-cell lung cancer cells and have the potential to regulate their growth [55]. Non-small-cell lung cancer appears to have fewer recognized growth factors, although epidermal growth factor and transforming growth factor  $\alpha$  have been shown to bind to specific cell receptors and to stimulate growth [55,61]. The expression of growth factors and their receptors in some non-small-cell lung cancers appears to be related to aggressive clinical behaviour and the increased likelihood of a

**Fig. 41.7** Undifferentiated large-cell carcinoma showing large pleomorphic tumour cells (haematoxylin & eosin  $\times 305$ ).

**Fig. 41.8** Autocrine growth stimulation: a lung cancer cell produces a growth factor that binds to a receptor to stimulate proliferation.

response to chemotherapy. Results of clinical trials involving the manipulation of these autocrine growth factors are eagerly awaited.

### Genetic abnormalities

It is surprising that only 15% of male smokers contract lung cancer, given the close association between smoking and the disease. It seems likely that the remaining 85% have an inherited resistance to the disease and that the small number of non-smokers who develop lung cancer may be inherently susceptible [62]. This has led to much interest in genetic abnormalities in patients with lung cancer and in laboratory models of the disease [63]. A plethora of genetic abnormalities has been detected and this has created some confusion as to their significance in the genesis and progression of the disease. One of the earliest and most consistent chromosomal deletions seen is the loss of the short arm of chromosome 3 (p14–p23) in small-cell lung cancer [64,65]. This suggests that loss of specific gene function may be a critical step in the development of lung cancer. This model certainly seems to fit for the development of another, rarer tumour, retinoblastoma, where a specific tumour suppressor gene is also lost from chromosome 3, and indeed there is a close association between small-cell lung cancer and retinoblastoma [66]. Similar genetic abnormalities are seen in tumour cells from non-small-cell cancers [67,68], although the situation is less striking and inactivation of the *CDKN2* gene on chromosome 9 may be more important in this histological subtype [69].

### Oncogenes

Activation of small parts of the genetic code is seen in many cancers and the role of these oncogenes is unclear. Members of the *myc* gene family are often activated in lung tumours, particularly of small-cell type, and may be associated with increased aggressiveness of tumour growth [70]. The normal function of these genes has remained elusive and it is not clear how overexpression contributes to tumour growth. Activation of the *K-ras* oncogenes is usually detected in adenocarcinoma of the lung and patients carrying these mutations have been

shown to have a more aggressive clinical course [71]. It is to be hoped that a greater understanding of the importance of oncogenes will lead to innovative therapies for the patient [63,70,72].

### Tumour markers

Tumour markers are substances produced by tumour cells that are released into the bloodstream where they can be measured. They may be helpful in screening and in the early diagnosis of cancer, in an assessment of the extent of disease and in response to treatment. Many of these markers are produced by normal cells, for example neurone-specific enolase, creatine phosphokinase BB and carcinoembryonic antigen. A long list of tumour-associated antigens has also been discovered. However, despite the deliberations of large international workshops in this field [73], the large variations in sensitivity and specificity of all these compounds has made their precise clinical usefulness uncertain [74,75].

## Clinical features

### Common modes of presentation

Patients with lung cancer can present in many different ways. The majority of patients present as the result of the investigation of some new respiratory symptom or because their pre-existing respiratory state has worsened. A small percentage have no respiratory symptoms and the diagnosis is made by the chance finding of an opacity on a chest radiograph ordered for some other reason. A third group develop non-specific symptoms of malignancy, including malaise, anorexia and weight loss. A fourth group presents as a result of metastatic disease and usually have an extremely poor prognosis.

### Central tumours

Three-quarters of patients with lung cancer have their primary disease in the central airway. This is especially true of squamous and small-cell carcinomas. The commonest symptoms at presentation are cough, haemoptysis, dyspnoea and chest pain, either alone or in

combination. Cough is by far the most common symptom at presentation and any 'new' cough that persists longer than 2 weeks should be regarded with suspicion, especially in patients over the age of 40 years who are tobacco smokers. Unfortunately this group tend to have a chronic cough due to chronic bronchitis and this may often lead to some delay in diagnosis. Haemoptysis is usually an alarming symptom for the patient and one that should always be thoroughly investigated. It may amount to only minimal streaking of blood in mucoid sputum and the patient often presents in order to be reassured. Copious haemoptysis is uncommon. However, it should be recognized that most patients who have haemoptysis do not have lung cancer; nevertheless all patients with this symptom require investigation. Breathlessness may arise because of central airway narrowing or because of partial or complete collapse of a distal segment of lung. Poorly localized deep chest discomfort occurs in up to 60% of patients at diagnosis. The exact cause of this symptom in patients with centrally placed tumours is unclear but it may be due to involvement of peribronchial or perivascular nerves.

### Peripheral tumours

Peripheral neoplasms, commonly adenocarcinoma or large-cell types, often have a different mode of presentation. They may cause no respiratory symptoms at the time of diagnosis, which may follow a chest radiograph taken for some other reason or as part of the investigation of non-specific symptoms. Cough and haemoptysis are less common than in central lesions. Cough with large amounts of mucoid sputum (bronchorrhoea) is described in 10% of cases of bronchioloalveolar carcinoma, although this is an unusual symptom [76]. Dyspnoea is also less common and if present is likely to be due to either pleural involvement with tumour or blockage of lymphatics in lymphangitis carcinomatosa. Pleural effusion also causes breathlessness if it is large enough to compress the lung. Adenocarcinoma is particularly noted for seeding the pleura. Spread beyond the pleura into the chest wall produces dull, continuous pain that commonly interferes with sleep.

### Distant spread

Approximately one-third of patients with lung cancer present with symptoms due to metastatic spread outwith the thorax. Skeletal metastases, which are most commonly seen in small-cell and large-cell lesions, may present with bone pain and even pathological fractures. Cerebral metastases may present with progressive neurological symptoms and are common in patients with widespread disease. Cervical lymph gland and adrenal involvement are also common but do not usually produce symptoms.

Spread to the liver similarly rarely produces symptoms unless the metastases are large.

### Common clinical findings at presentation

Frequently, physical examination of the chest in a patient with lung cancer reveals no abnormal signs. However, physical signs may be elicited that are helpful for not only reaching a diagnosis but also making a preliminary assessment of the extent of disease and determining the most appropriate sequence of further investigation and perhaps treatment in an individual case. For instance, if the patient is obviously breathless while undressing this is usually an indication of coexisting chronic obstructive airways disease, which may preclude attempts at surgical treatment.

The hoarse voice of vocal cord paralysis is easily detectable and may be the only complaint of the patient. When asked to cough the patient often produces a relatively ineffectual expiratory noise, the so-called 'bovine cough'. This lacks the explosive quality of a normal cough produced by proper juxtaposition of two fully adducted cords. The left recurrent laryngeal nerve is most commonly involved as it loops round the aortic arch where it passes over the left main bronchus, a site that may be involved directly by tumour or by mediastinal lymph node metastases. Involvement of the right recurrent laryngeal nerve indicates a thoracic inlet tumour or invasion of the cervical nodes since the nerve loops around the right subclavian artery in the root of the neck. Vocal cord paralysis is therefore only seen in irresectable tumours because of mediastinal involvement.

Clubbing of the fingers and toes is commonly seen, although in one series was not present in patients with small-cell lesions [77]. The cause is unknown and may be associated with hypertrophic osteoarthropathy (discussed below).

Lymphatic spread is common and the scalene and supraclavicular lymph glands are usually the first to become enlarged. Axillary lymph glands are rarely involved and indicate invasion of the chest wall. The palpation of a lymph node provides ready access for histological sampling and positive histological confirmation indicates inoperability also.

Narrowing of the trachea or a lesion in either main bronchus at the level of the carina may cause stridor, an easily audible sound during inspiration. With more distally placed obstructing tumours this sound assumes the quality of a wheeze, which may be audible without a stethoscope. It may persist despite coughing, implying the presence of a fixed mechanical obstruction. A central obstructing lesion may cause a decrease in the intensity of breath sounds over a lobe or entire lung. Such patients are likely to develop atelectasis of the affected portion of lung if treatment is delayed.

The presence of a pleural effusion in a patient with lung cancer is more likely to be due to neoplastic pleural involvement than to be secondary to complicating infection or some other process. A pleural friction rub may be heard over an area of pleuritic pain.

About 5–10% of patients may present with symptoms due to obstruction of the superior vena cava (SVC). The patient notices swelling of the face and neck with tightness around the collar, which may progress to gross oedema. Occasionally the patient may be misdiagnosed as having an allergic reaction, especially if persistent flushing of the face is seen. The earliest and most common sign is bilateral jugular venous engorgement and superficial varicosities over the area drained by the SVC. Obstruction of the SVC is caused by either mediastinal lymph node metastases or direct venous compression of a tumour in the right upper lobe.

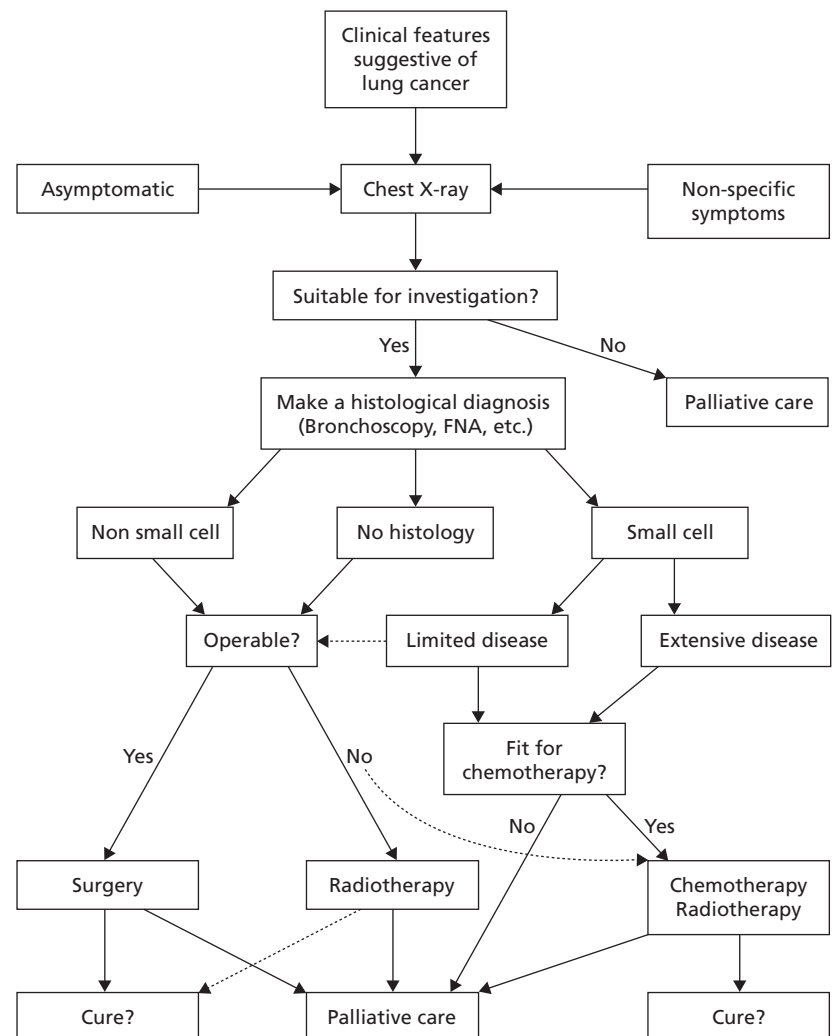

Dullness to percussion at a lung base may be due to not only perfusion or collapse but also to a raised and paralysed hemidiaphragm. This may be confirmed

radiologically or on ultrasound by the presence of paradoxical movement on sniffing and it may contribute significantly to dyspnoea. The majority of cases of phrenic nerve paralysis indicate widespread mediastinal involvement.

A palpably enlarged liver due to hepatic involvement is an unusual finding at presentation, as are the symptoms and signs of raised intracranial pressure resulting from cerebral spread. Dysphagia due to mediastinal node compression of the oesophagus is also a late symptom. The clinical features of superior sulcus (Pancoast) tumours and paraneoplastic syndromes are discussed below.

## Investigation

Clinicians faced with the management of a patient with a likely bronchial carcinoma need to instigate investigations in order to allow a rational management plan for that patient (Fig. 41.9). The purpose of any investigations performed are to confirm the clinical diagnosis, including if possible the histological type, and also to assess the extent

**Fig. 41.9** Outline of the investigation and management of patients with lung cancer. (FNA, fine-needle aspiration.)

or stage of the disease in order to plan the most appropriate management. Clearly the complexity of investigations should correlate with the patient's suitability for active treatment. Lung cancer commonly presents at an advanced stage in predominantly older patients who often have other significant medical conditions related to cigarette smoking, and in the past there was a feeling that investigating these patients was not justified as effective treatment was not available. However it is now felt that obtaining a precise diagnosis helps patients come to terms with their disease and allows some indication concerning prognosis to be given to them and their families. In most countries the initial assessment of lung cancer patients is performed by respiratory physicians [78], and a case is now developing for recommending that all patients with the possible diagnosis should be assessed by a team involving respiratory physicians as well as clinicians who may be responsible for further treatment, such as cardiothoracic surgeons and oncologists.

### Chest radiography

The chest radiograph is nearly always abnormal in

patients with lung cancer at presentation [78]. Common early findings include slight prominence of a hilar shadow in the case of a central tumour and a small pulmonary nodule in the case of a peripheral tumour [79]. By the time the patient presents with symptoms there is more commonly obvious unilateral hilar or perihilar enlargement that is highly suggestive of a primary carcinoma or hilar lymph node spread (Fig. 41.10). Often it may be difficult to distinguish between a prominent hilar shadow due to a normal but prominent pulmonary vessel and an early central tumour.

More peripherally situated lung cancer usually produces a homogeneous mass shadow. The margins are often poorly defined so that they may be mistaken for inflammatory disease. The average diameter of rounded lesions at presentation is 3–4 cm; lesions of less than 1 cm in diameter are likely to be missed [80]. When central necrosis in the tumour occurs, cavitation may be evident and this is most commonly seen in squamous carcinomas [81]. Cavitation is not a feature of small-cell carcinoma. The inner lining of the cavity is often irregular and the shadow may be indistinguishable from that produced by a lung abscess, particularly if a fluid level is present

**Fig. 41.10** Chest film of 60-year-old woman with left hilar squamous tumour arising at the origin of the upper lobe bronchus and causing some distal consolidation.

**Fig. 41.11** Irregularly cavitated carcinoma in right upper lobe. The fibrosed left upper lobe was due to the after-effects of tuberculosis.

(Fig. 41.11). Bronchial obstruction by tumour may produce a true lung abscess, although consolidation without cavitation is more common.

Frequently the most striking radiographic features in lung cancer are the result of the mechanical effects of the tumour which, by obstructing a bronchus, may cause total or partial collapse of a segment, lobe or lung (Fig. 41.12). An ipsilateral unaffected lobe tends to overinflate, becoming more lucent as it expands to fill the additional space provided by the area of collapse, and characteristic displacement of interlobar fissures may be seen. Extensive atelectasis or consolidation may conceal the central causative lung cancer, as may a large pleural effusion.

Elevation of one or other hemidiaphragm may indicate phrenic nerve paralysis. This may be confirmed by fluoroscopy or ultrasound when paradoxical movement of the paralysed leaflet is seen on sniffing. Mediastinal lymph node involvement is often not radiographically visible on plain films unless very advanced, in which case widening of the mediastinum may be seen. In a few cases, lymphatic spread may extend from mediastinal or hilar nodes to pulmonary lymphatics, producing fine, lace-like shadows that may involve the whole of both lung fields, a form of dissemination known as lymphangitis carcinomatosa [82] (Fig. 41.13).

The radiographic features of bronchioloalveolar carcinoma

are frequently indistinguishable from those of other histological types. However, this tumour may sometimes produce diffuse ill-defined fluffy infiltrates resulting from its tendency to spread along the airways at bronchiolar level [83] (Fig. 41.14). Radiographically this may resemble pneumonic consolidation but it obviously does not respond to standard antibiotic therapy.

Carcinomas at the extreme apex of the lung are known as Pancoast, thoracic inlet or superior sulcus tumours. In their early stages they may produce only a thin rim of shadowing at the apex that is indistinguishable from pleural thickening due to other causes. As these tumours enlarge, they may also erode and destroy adjacent ribs and infiltrate nerves of the brachial plexus to produce the familiar clinical syndrome (Fig. 41.15).

It is possible, although unusual, for a patient with lung cancer to have a normal chest radiograph [78,84]. This usually occurs when a primary tumour is small and central. Such patients require further investigation, usually by bronchoscopy, if there are other clinical features suggesting bronchial carcinoma, such as haemoptysis.

### **Sputum cytology**

The examination of sputum expectorated by patients suspected of having lung cancer is a simple investigation to

**Fig. 41.12** Complete collapse of the right lung secondary to main bronchial tumour. Note tracheal deviation and absence of air bronchogram in right lung.

perform and often a valuable diagnostic aid. In experienced hands a definitive diagnosis of lung cancer may be made in 60–70% of all cases in whom the diagnosis is subsequently confirmed histologically [84]. The likelihood of this test being positive increases when the tumour is centrally placed, with increasing tumour size and when the lesion is situated in the lower lobe [85,86]. Not surprisingly, squamous and small-cell tumours, which are usually central, have a higher positive yield. Establishment of the correct histological group by sputum cytology has an accuracy of 50–80% depending on the degree of differentiation. Poorly differentiated tumours are more difficult to subtype [84].

The collection of adequate samples is extremely important. The first sputum in the morning or one produced after a bronchoscopy tends to produce a higher positive yield. The yield from a single sample in patients with lung cancer is approximately 40%, although this can be increased by repeated collections to in excess of 80% with four specimens [87]. In experienced hands, false-positive results do not usually exceed 1%.

### Bronchoscopy

Bronchoscopy is the most useful investigation in the evaluation of a patient suspected of harbouring a lung cancer, as it can provide histological confirmation as well as information regarding the extent of the disease. The

procedure itself is discussed fully in Chapter 8. Tumours that are situated centrally on a radiograph may be visible bronchoscopically as a neoplastic mass within the lumen. Frequently the presence of a tumour is indicated by bronchial stenosis or external compression due to surrounding tumour tissue or lymph node metastases.

Tumours that are beyond bronchoscopic vision may be biopsied using the transbronchial technique or by blind brushings and washings. Positive diagnoses have been made in 60% of such lesions when they are greater than 2 cm in diameter [88]. Techniques have also been developed for transbronchial needle aspiration of mediastinal nodes [89].

Bronchoscopic evidence of inoperability is provided by the endobronchial site of the tumour and any evidence of mediastinal involvement. Tumours confined to a lobar bronchus may be removed by a lobectomy but those growing to within 1 cm of the carina require pneumonectomy. Mediastinal involvement is suggested by a paralysed vocal cord and by widening of the main carina due to subcarinal lymph node enlargement. External compression of the lateral wall of the lower trachea by enlarged paratracheal lymph nodes also suggests inoperability, assuming that the lymph nodes are involved with tumour. Previously it was common practice for thoracic surgeons to repeat a physician's bronchoscopy prior to surgery. Modern bronchoscopic techniques involving video imaging may allow the surgeon to view the bronchoscopic

findings and perhaps save the patient from a repeat procedure.

### Other initial investigations

The vast majority of patients have blood tests as part of their initial assessment [78]. These provide no diagnostic information, although they may point to hepatic involvement or the presence of a paraneoplastic endocrine syndrome (see below). In patients with peripheral lesions a definitive histological diagnosis may only be obtained by percutaneous needle biopsy of the lung or pleura, by aspiration of subcutaneous swellings, lymph nodes or pleural fluid, or by aspiration or biopsy of distant metastases in bones, liver, adrenals, etc. Intrathoracic disease may be confirmed at thoracoscopic lung biopsy, mediastinoscopy or thoracotomy (see below).

### Determination of operability

Once a diagnosis has been made, the investigation of a patient with lung cancer is aimed at deciding the most appropriate therapy available for that individual. Surgical resection has the greatest impact on survival, although at the time of diagnosis the majority of patients are clearly inoperable. If the patient is a prospective surgical candidate, further evaluation has to be carried out in order to ensure that he or she is fit for an operation and that metastatic disease, which would render the patient incurable despite removal of the primary lesion, is excluded.

### Assessment of fitness for surgery

It is common for the lung function of patients with carcinoma of the bronchus to be impaired, as a result of total or partial occlusion of a large bronchus by a central lesion and because of coexisting chronic bronchitis and emphysema which, like lung cancer, are causally related to cigarette smoking. Careful consideration must be given to the effect of the removal of *functional* lung tissue in the tumour-bearing lung in order to prevent, at worst, postoperative respiratory failure and even death or, at best, extreme and persistent dyspnoea that would greatly impair the patient's level of physical activity and quality of life.

The forced expiratory volume in 1 s ( $FEV_1$ ) and forced vital capacity are simple to measure, reproducible and form the basis of the most reliable predictable measurement in the evaluation of suitability for lung resection. Studies have shown that the risk of postoperative chronic ventilatory insufficiency is high if the postoperative  $FEV_1$  is less than 1 L [90], although allowance for the height of the patient should be made in view of the increasing numbers of women presenting with lung cancer. Spirome-

try is reduced by approximately 10–15% of predicted values as a result of lobectomy and by 20–30% with pneumonectomy; in general, patients with a preoperative  $FEV_1$  exceeding 2 L tolerate surgery without severe postoperative breathlessness. Patients who are considered marginal for surgery require further investigation. A quantitative assessment of regional lung function may be useful in borderline patients. It may demonstrate that the patient has already undergone the physiological equivalent of a pneumonectomy or lobectomy by virtue of the tumour occluding a main or lobar bronchus. In such situations resection may do nothing to worsen lung function and may even produce physiological improvement by removing a major cause of ventilation-perfusion mismatch. There is no consensus about the best method of carrying out split lung function studies but most rely on radioisotopes [91,92].

Other useful tests that can be performed preoperatively include the measurement of diffusing capacity, since it is known that postoperative complications are more common if this is less than 40% of predicted before the operation [90]. Most clinicians place considerable reliance on the history of breathlessness and observation of the patient, for example, breathlessness while undressing is a good indication that the patient will be more breathless after surgery, unless of course the tumour has already caused a physiological pneumonectomy. The original lung function test prior to pneumonectomy, carried out by the pioneers of this operation, was to induce an artificial pneumothorax and observe the patient! Nowadays, a 6-min walking test gives a good indication of preoperative function, and difficulty completing this test at a reasonable pace should cause one to think twice before advising surgery.

Consideration also needs to be given to other medical conditions, such as ischaemic heart disease and peripheral vascular disease. Patients who have well-controlled angina usually need to undergo an exercise ECG test and any significant abnormality may need further evaluation with coronary angiography. Subjects whose exercise tolerance is limited by significant intermittent claudication are usually not deemed good surgical candidates.

### Assessment of local spread

Evidence of spread of tumour into local structures and the mediastinum may be obvious from a history of dysphagia, hoarseness or obstruction of the SVC. A pleural effusion usually means that the subject is inoperable, although it should be further evaluated with pleural aspiration and biopsy. Some centres do not exclude patients if the effusion is small and does not contain malignant cells on repeated aspiration. However, results of surgery in these patients is poor.

The results of surgery correlate well with the extent of

mediastinal node involvement (see below) and assessment of the mediastinum is essential in all patients being considered for surgery. While the initial chest radiograph may show obvious mediastinal lymphadenopathy, a normal mediastinal appearance on a plain radiograph still requires the patient to undergo further mediastinal evaluation.

### *Computed tomography*

Computed tomography (CT) (Fig. 41.16) is now established as the best non-invasive method for assessing the mediastinum in patients with lung cancer being considered for resection [93]. Technological advances over the last two decades, with the introduction of much faster scanners, have enhanced the sensitivity of the investigation (see Chapter 7). The most important limitation of preoperative CT is the fact that although it is good at detecting enlarged lymph nodes, it cannot distinguish between neoplastic and reactive nodes, nor can it tell whether a normal-sized lymph node contains microscopic deposits of tumour. Studies that have measured the sensitivity and specificity of preoperative CT compared with mediastinal node sampling at either mediastinoscopy or thoracotomy show considerable variability in sensitivity and specificity [94–96]. Earlier studies were limited by the technical ability of the available scanners, although many studies using modern machines have given comparable results. A meta-analysis of over 40 studies published in 1990 showed a sensitivity of 79% and a specificity of 86% [97]. The authors used 1 cm as the cut-off value for normality, while most reports assume a 1.5-cm diameter as the upper limit of normal. There is a correlation between nodal size and the likelihood of malignancy, although the association is fairly weak. In one study [94] only 13% of 336 nodes less than 1 cm in diameter contained metastases, while 36% of 78 nodes greater than 1 cm were malignant.

**Fig. 41.16** Thoracic CT showing three enlarged lymph nodes at the level of the aortic arch.

Even in the group with very large nodes (>2 cm in diameter) only two-thirds were subsequently found to contain tumour. While a normal-sized node may well contain a small focus of tumour cells, the predictive value of a negative result on CT has been shown to be in the order of 90%. However, a recent study [98] has questioned this value, finding mediastinal lymph node metastases in 19 of 90 patients (21%) with non-small-cell lung cancer who underwent thoracotomy and who had normal-sized nodes (<1 cm) on CT.

A consensus view about the place of preoperative CT in non-small-cell lung cancer is now emerging. Patients with abnormal scans require mediastinal lymph node sampling to confirm malignant involvement. This allows a significant number of patients to undergo successful thoracotomy who might otherwise have been denied surgery by the presence of enlarged lymph nodes on their scan. Patients with a negative scan who are otherwise operable should proceed directly to thoracotomy, although mediastinal lymph nodes should be sampled at the time of operation. CT may also be useful for identifying tumour invasion of the mediastinum and pleura [99] but its main role would appear to be in detecting which patients should have mediastinoscopy prior to surgery.

Magnetic resonance imaging (MRI) may be useful in assessing Pancoast tumours and chest wall invasion but appear to have no specific advantage over CT in the routine evaluation of a patient. Likewise the place of positron emission tomography has not been established in lung cancer [100] and it is not widely available to most clinicians.

The use of radioactive isotopes taken up by tumour cells, such as gallium, has been evaluated but adds nothing to the sensitivity or specificity of CT. A major advance in this field would be the discovery of a technique by which malignant tissue could be discriminated from non-malignant tissue, therefore allowing accurate documentation of tumour spread.

### *Mediastinoscopy*

As stated above, patients who have abnormal mediastinal nodes on CT should have mediastinoscopy to confirm or refute the presence of metastatic spread. This allows for better selection of patients for surgery, since those with metastatic disease can be excluded and those with enlarged benign nodes can proceed to operation. Mediastinoscopy can thus improve the survival figures of surgical patients, although in the UK it is not universal practice among thoracic surgeons to sample the mediastinum preoperatively [78,101]. Mediastinoscopy cannot increase the number of patients cured by surgery but can prevent some futile operations being performed on some patients.

For anatomical reasons it is not possible for the surgeon to sample the whole of the mediastinum at medi-

astinoscopy and false-negative rates of around 10% are recorded [100]. Complications are not usually significant and mortality is rare. Some surgeons prefer to perform an anterior mediastinotomy if access is required to sample nodes draining into the left upper lobe or the anterior segment of the right upper lobe. It is also possible to sample periaortic and subaortic glands by this route.

### Assessment of distal spread

Spread of bronchial carcinoma to a site outside the thorax, such as the brain, liver or skeleton, clearly makes a patient inoperable. Patients who have abnormal biochemical tests or specific symptoms that may point to evidence of distant spread should have further evaluation.

### Liver metastases

The finding of an obviously enlarged, hard and irregular liver on physical examination is strong evidence of hepatic metastases. However, this is unusual at presentation, as is jaundice. Liver function tests should be requested routinely on all patients requiring staging of lung cancer. Although normal values do not exclude hepatic spread and elevated values may be due to non-metastatic liver disease, further investigations are required if the patient's management is likely to be affected as a result. Liver ultrasound and CT have a similar degree of accuracy in the detection of hepatic metastasis [102]. In the UK, it has become routine practice for radiologists to include the liver (and adrenal glands) when asked to perform CT of the thorax to assess operability. Occasionally, if there is doubt about the presence of hepatic involvement, histological clarification may be obtained by fine-needle aspiration or liver biopsy, either of which can be performed under ultrasound or CT guidance.

### Bone metastases

The skeleton is a common metastatic site for bronchial carcinoma. Usually these metastases are symptomatic, and pain suggestive of a bony metastasis should lead to radiographs of the affected area. Lytic lesions are usually seen on these films. Isotope bone scanning is much more sensitive than conventional radiography in the detection of bony metastasis, false-negative rates being less than 2% (Fig. 41.17). The main disadvantage of bone scanning is its lack of specificity. False-positive rates of 40–50% have been reported, the increased uptake presumably being due to benign metabolic bone disease [103,104]. It is known that patients who are asymptomatic and have no biochemical abnormalities have a truly negative bone scan in more than 95% of cases [105]. It seems clear therefore that there is no place for routine bone scanning in all patients pre-operatively and that this investigation should be reserved

**Fig. 41.17** Bone scan showing multiple spinal, shoulder girdle and rib metastatic deposits.

for those in whom there is clinical or biochemical evidence to suggest skeletal spread. As with liver metastases, occasionally it may be necessary to obtain further information with local biopsy.

Patients with small-cell carcinoma have a much higher incidence of bony metastases and in this situation scans may be useful to document both the extent of disease and its response to chemotherapy [106].

### Brain metastases

Intracranial spread may come to light as a result of headache, vomiting, personality change or fits, or because of the development of focal neurological deficit. Occasionally, intracranial metastases present at a stage when the lung primary is neither symptomatic nor even radiologically apparent, the diagnosis being made retrospectively after craniotomy. When cerebral metastases are suspected as a result of these clinical features, the investigation of choice is CT with contrast enhancement. Routine CT of the brain in asymptomatic patients gives a very low yield (approximately 2%) [107] and is not indicated as a screening procedure.

The likelihood of detectable intracranial metastases being present at the time of diagnosis varies according to cell type, being most common in patients with small-cell carcinoma. In one necropsy study, the frequency of cerebral metastases varied from 14% in squamous cell tumours to 31% in small-cell lesions [108]. The clinician therefore may have a much lower threshold for requesting this investigation in patients with small-cell lesions.

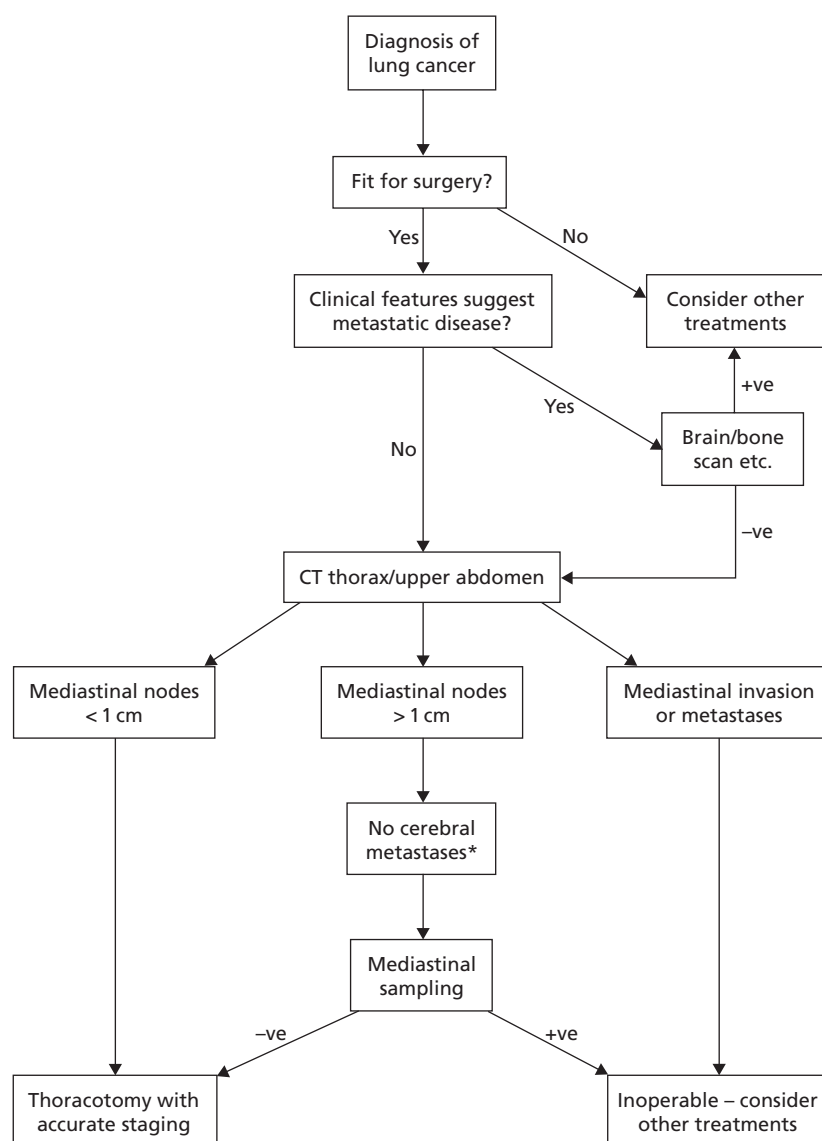

### A routine preoperative management plan

The assessment of suitability for resection is an important part of the management of lung cancer patients, as this form of treatment offers the best chance of significant prolongation of survival. The various steps in this management process are illustrated in Fig. 41.18. Patients should have a definite diagnosis, with histological subtype if possible, prior to evaluation. Those with small-cell lesions are usually more suitable for systemic treatment with chemotherapy (see below). The place of surgery in patients with small-cell lesions is controversial and clinicians considering this form of treatment in these patients should conduct a comprehensive search for metastatic disease.

Patients thought to be fit for surgery, with no symptoms or signs to suggest metastatic disease, should undergo CT

of their thorax and upper abdomen. Those patients without significant mediastinal node enlargement (<1 cm) should proceed directly to thoracotomy. Those with mediastinal invasion or metastases are inoperable and should be assessed for other forms of therapy. Patients with enlarged lymph nodes should have mediastinal sampling at mediastinoscopy. Positive nodes at this stage make the patient inoperable. Patients with a negative mediastinoscopy should proceed to thoracotomy.

A more vexed question is the role of CT of the brain and bone in otherwise operable patients. Hillers and colleagues [109] performed a meta-analysis in order to determine the proportion of patients with potentially operable non-small-cell lung cancer who could have been spared thoracotomy by these investigations. They concluded that fewer than 5% of patients thought operable on previous CT of the thorax had evidence of distant metastases on

**Fig. 41.18** Management of a potentially operable patient (see text on cerebral metastases).

scans. However, the likelihood of metastatic disease increases if the mediastinum has been found to be abnormal preoperatively. For instance in one study [107], 4% of patients with normal CT of the thorax had occult metastases compared with 32% who had an abnormal mediastinum on CT.

Muers, in his excellent reviews of the situation [110,111], concluded that patients with a normal mediastinum should not undergo routine brain and bone scanning as 95% of them are normal. Patients with enlarged mediastinal nodes should be investigated. They should have a bone scan if they have suggestive symptoms or biochemical abnormalities and he also recommends that they should have CT of the brain. Clearly the decision is between mediastinal sampling or scanning of distant organs. The latter is certainly cheaper and can be done on an outpatient basis. There is a clear need for large multi-centre trials to try to clarify this situation.

## Staging

The clinical staging of lung cancer is an attempt to define the anatomical extent of the tumour. Staging has been used primarily as a means of allowing management decisions to be based on published data relating to survival of clearly defined groups or 'stages'. Separate systems have evolved for non-small-cell and small-cell tumours.

### Non-small-cell lung cancer

Patients with non-small-cell lung cancer are staged by the application of a process using 'T' for primary tumour, 'N' for regional lymph nodes and 'M' for distant metastases. Each letter is qualified by numerical suffixes that describe the size or local extent of the tumour, the extent of regional lymph node spread if present, and the presence or absence of distant extrathoracic metastases. The use of such a TNM system in non-small-cell lung cancer has shown that the stage of the tumour clearly influences prognosis [112]. The TNM staging classification currently in use was upgraded in 1997 and is presented in Table 41.6 [113]. The various TNM classifications have been divided into stages I–IV. Stage III is split into stage IIIA, which accommodates the potentially operable T3 and N2 patients, and stage IIIB, which contains inoperable patients whose disease may be controlled locally by thoracic radiotherapy. Stage I and II tumours are clearly operable, while patients in stage IV have distant metastases. It can be seen from Fig. 41.19 that this staging classification clearly separates the different prognostic groups and allows accurate prediction of survival at the time of diagnosis. The clinical methods used for establishing the stage of lung cancer have been described above. Providing that staging has been thorough, the number of patients found at thoracotomy to be

**Table 41.6** TNM definitions in the international staging system for lung cancer. (From Mountain [113].)

Extent of primary tumour (T)				
T0	No primary tumour detected.			
Tis	Carcinoma <i>in situ</i> .			
TX	Primary cannot be assessed / positive cytology only.			
T1	A tumour 3 cm or less in greatest dimension, surrounded by lung or visceral pleura, not in main bronchus.			
T2	A tumour more than 3 cm in size, or in main bronchus more than 2 cm from main carina, or invading visceral pleura, or associated with partial atelectasis (not entire lung).			
T3	Involves any of following: chest wall (including superior sulcus), diaphragm, parietal pericardium, mediastinal pleura. In main bronchus less than 2 cm from main carina (but not involving it), atelectasis of entire lung.			
T4	Invasion of mediastinum, heart / great vessels, trachea, carina, oesophagus, vertebral body. Separate nodules in same lobe as primary, malignant pleural or pericardial effusion.			
Condition of regional lymph nodes (N)				
NX	Regional lymph nodes cannot be assessed.			
N0	No regional lymph node metastases.			
N1	Ipsilateral peribronchial or hilar nodes involved.			
N2	Ipsilateral mediastinal or subcarinal nodes involved.			
N3	Contralateral hilar or mediastinal nodes involved, or any scalene / supraclavicular nodes involved.			
Presence or absence of distant metastases (M)				
MX	Distant metastases cannot be assessed.			
M0	No distant metastases.			
M1	Distant metastases, includes separate nodule in different lobe.			
Stage groupings (5-year survival rates in parentheses)				
Stage 0	Tis	N0	M0	(?)
Stage IA	T1	N0	M0	(60%)
Stage IB	T2	N0	M0	(38%)
Stage IIA	T1	N1	M0	(34%)
Stage IIIB	T2	N1	M0	(24%)
	T3	N0	M0	(22%)
Stage IIIA	T1	N2	M0	(13%)
	T2	N2	M0	(13%)
	T3	N1–2	M0	(9%)
Stage IIIB	T4	N0–2	M0	(7%)
	T1–4	N3	M0	(3%)
Stage IV	Any T	Any N	M1	(1%)

inoperable should not exceed 5%. A few are found to have N2 disease when macroscopically involved mediastinal nodes are beyond the reach of the mediastinoscope. Such patients may still undergo surgery but have a 5-year survival of around 10% [113]. Although it is not widespread practice, it is recommended that surgeons should methodically sample and separately submit lymph nodes from differently numbered mediastinal gland groups and

**Fig. 41.19** Cumulative proportions of patients with lung carcinoma surviving 5 years, by clinical stage of disease. (From Mountain [113] with permission.)

from the hilum in order to allow pathological staging following thoracotomy. In general, pathological staging (pTNM) tends to downgrade the preoperative stage by finding previously undetected disease, and it is not surprising therefore that the median survival of pTNM subsets is much better than that of equivalent TNM stages based on clinical investigations [113].

### Small-cell lung cancer

Small-cell lung cancers grow more aggressively and often metastasize earlier from a much smaller primary than other cell types; because of this, the TNM system of staging is irrelevant for small-cell tumours. Clinicians have adopted a simple staging system using the terms 'limited' and 'extensive' disease. Limited disease refers to a group of approximately 30% of patients who at presentation appear to have disease confined to the ipsilateral hemithorax (lung, pleura, and hilar, mediastinal and supraclavicular lymph nodes). Extensive disease refers to spread beyond these confines.

Since the majority of patients with small-cell tumours have inoperable disease at presentation, systemic therapy with drugs, to which the tumour is initially fairly sensitive, has become the mainstay of treatment. However,

there is a small subgroup of patients who do present with operable disease and they should be considered for operation in the standard way using routine staging procedures. It would seem reasonable to perform fairly intensive investigations for metastases in this group of patients, including CT of the thorax, upper abdomen and brain, as well as bilateral iliac crest marrow aspiration since bone marrow deposits are common in small-cell lung cancer. However, the natural history of small-cell lung cancer means that prolonged investigation delaying treatment may leave some patients unfit for active intervention.

In the same way as the TNM staging system gives a useful prognostic guide in non-small-cell lung cancer, disease extent (limited or extensive) is also a useful prognostic aid. Other factors influencing prognosis are a measure of the patient's ability to function (performance status) and a few simple biochemical investigations (serum sodium, and a measure of liver function such as lactate dehydrogenase or alkaline phosphatase). It can be seen therefore that in a patient with known small-cell lung cancer, taking a history, performing a clinical examination and arranging a simple blood test and chest radiograph are all that is required to give a fairly accurate guide to prognosis [114].

### Treatment

When discussing the current treatments available for patients with lung cancer it is relevant to divide the subject into the management of non-small-cell and small-cell types. As stated above, these two groups of patients have different prognoses and their tumours respond differently to the currently available therapies. The majority of patients have non-small-cell tumours and the treatment modality that gives the best result is still surgery. However, most patients are inoperable and palliation is the aim of any treatment offered. In this respect radiotherapy is very helpful; indeed, some patients who are not suitable for surgery may be treated with radical radiation therapy. The role of chemotherapy in non-small-cell lung cancer is controversial but is gaining acceptance, especially in North America.

Chemotherapy gives the best hope of prolonged survival and improved quality of life in patients with small-cell lesions. The tumour is radiosensitive, although the exact place of radiotherapy is not clear. There is a small subgroup of patients who are operable and their survival is as good as that seen with the best chemotherapy results. However, long-term survival in patients with this tumour is rare.

The place of different treatment modalities in the overall management of patients with lung cancer is outlined in Fig. 41.9. For the majority of patients, an attempt at curative therapy is not possible and efforts should be

directed towards palliation of the patient's symptoms. Quality of life is a term that is seen more commonly in studies of the treatment of lung cancer and is something that clinicians are now attempting to measure and to influence.

### **Non-small-cell lung cancer**

The prognosis for patients diagnosed with non-small-cell lung cancer is poor, most large series of unselected patients giving an overall 5-year survival of less than 10% irrespective of treatment [115]. This figure has not changed over the last 30 years [116] and the best results are in patients treated with surgery.

### **Surgery**

Although surgery is effective treatment for bronchial carcinoma, unfortunately the disease is only operable in a small minority of patients. Upwards of two-thirds of patients are inoperable at the time of presentation because of advanced age, poor respiratory function, other significant medical conditions or clinical evidence of tumour spread (see above). Of the remainder who are considered for surgery, 10–15% are rejected because of mediastinal involvement discovered at mediastinoscopy. Approximately 20–25% undergo surgery and up to 5% are found inoperable at thoracotomy. This means that only about 12–15% of all patients with non-small-cell tumours have a chance of receiving a potentially curable operation.

### **Types of operations**

Pneumonectomy involves ligation of the pulmonary veins, division of the pulmonary artery and suturing or stapling of the bronchial stump at the level of the carina. At lobectomy, corresponding vessels may be ligated at segmental level. Hilar and accessible mediastinal nodes should be removed at operation and labelled according to their site of origin in order to enable more accurate pathological staging. Serosanguineous fluid is allowed to accumulate in the empty haemothorax of patients undergoing pneumonectomy and this tends to stabilize the mediastinum. Following lobectomy, underwater seal drainage is mandatory to prevent the accumulation of fluid and to allow full expansion of the remaining lobe or lobes. As an alternative to pneumonectomy, a variety of bronchoplastic procedures have been devised to remove tumour and yet conserve part of the lung subtended by the involved bronchus. The most common of these procedures is 'sleeve resection' of a tumour, extending from the right upper lobe bronchus into the right main and intermediate bronchi. Anatomical considerations make such procedures less common on the left side. When sleeve resections are carried out, facilities for frozen section are required at

operation to ensure that both ends of the sleeve are clear of tumour.

When a peripheral pulmonary opacity is found at thoracotomy to be small and confined to a bronchopulmonary segment, the more limited procedure of segmental resection may be carried out, and it may be possible to perform this operation using a thoracoscope [117]. This procedure, which permits 'keyhole surgery' in the chest, allows much quicker rehabilitation postoperatively and a much shorter perioperative period in hospital. There is no large thoracotomy wound and postoperative pain is less of a problem. Some surgeons are concerned that thoracoscopic resections may be incomplete in malignant disease, although modern techniques have allowed for pneumonectomies to be carried out and it is possible to sample nodes in the mediastinum with this instrument [118]. The results of studies of long-term survival of larger series of patients operated on in this way are awaited with interest.

### **Complications**

Apart from the general complications that may beset any major surgical procedure, there are several problems peculiar to pulmonary resective surgery. Lower respiratory tract infection in residual lung tissue is common and requires treatment with appropriate antibiotics and physiotherapy. Postoperative infection of the resected space (empyema) can be a particularly difficult problem especially in an upper lobectomy. One or other of the phrenic nerves occasionally has to be sacrificed in a resection of a central tumour abutting the pericardium. The left recurrent laryngeal nerve may be similarly damaged during a left pneumonectomy.

Operative mortality has fallen over the years and is a reflection of better surgical techniques and the application of more stringent selection criteria. The intraoperative and 30-day postoperative mortality for over 2000 resections in 12 different North American centres carried out between 1979 and 1981 under the auspices of the Lung Cancer Study Group found the overall rate for pneumonectomy to be 6.2%, for lobectomy 2.9% and for segmental and wedge resections 1.4% [119]. Surgery in older patients used to be associated with a high mortality rate but published figures from the last decade have suggested an overall mortality of less than 6% [119,120]. The results of macroscopically complete resection in elderly patients justify active treatment, since the 5-year survival rate is about 35% [120]. It has become increasingly difficult to justify the decision that a patient is unsuitable for surgical resection on the grounds of age alone, provided the same careful staging procedures that are applied to younger patients are followed. It should also be remembered that the life expectancy in a developed country for a patient reaching the age of 70 is in excess of 10 years.

**Results**

Survival after resection for non-small-cell lung cancer is closely related to the stage and pathological type of disease. Stage I tumours (T1/T2N0M0) when treated surgically carry a 5-year survival rate of 40–60% [121,122]. In stage II tumours, the survival rate following operation falls to 20–50% depending on histology [122]. The survival of patients with stage IIIA disease is much poorer after surgery with between only 9 and 13% surviving for 5 years [123]. The overall 5-year survival figures for surgery for non-small-cell lung cancer is 35%. Patients with squamous cell tumours fare better than those with adenocarcinoma at all stages. Mountain [123] reported 4-year postoperative survival for stage IIB (T2N1) patients to be 53% for squamous carcinoma and 25% for adenocarcinoma, and for (T3N0) 37% and 21% respectively.

It is depressing that the vast majority of patients who die after resection do so from recurrent disease. The pattern of recurrence in surgically treated stage I and II disease was analysed by the Lung Cancer Study Group in a retrospective review of 771 patients [124]; 70% occurred initially outside the chest, presumably from occult distant metastases present at the time of surgical resection of the primary tumour.

**Radiotherapy**

Radiotherapy is most commonly used to achieve symptomatic relief when given in low palliative doses to patients who are clearly inoperable and have appropriate symptoms due to their disease. Radical radiotherapy may offer the chance of cure in a small proportion of patients with non-small-cell lung cancer who are considered unsuitable for surgery on medical grounds but otherwise have 'operable' disease. Treatments are usually administered by means of a megavoltage linear accelerator, with some centres still using a cobalt-60 source for palliative treatments. The collimated beams of ionizing radiation are positioned to produce a tumoricidal dose in an area where the beams cross, with as much sparing of normal tissue as possible. Tissue absorption of radiation is measured in grays (Gy), 1 Gy being equivalent to 1 J of energy absorbed per kilogram of tissue; the relationship between the SI unit (Gy) and the old unit (rad) is shown in Table 41.7. Radiotherapy is the most frequently employed treatment in

patients with non-small-cell carcinoma of the bronchus [78].

**Radical radiotherapy**

This term implies an intention on the part of the radiotherapist to employ a relatively large dose of treatment in order to increase the patient's survival time or even to achieve a cure. Patients with stage I and II non-small-cell lung cancer are best treated by surgical resection; however, if this form of treatment cannot be followed, either because an operation has been declined or because of some medical contraindication, then radiotherapy does offer a small chance of cure. It should be recommended provided that the patient's general condition is good and that he or she has sufficient ventilatory capacity to survive the loss of functioning lung tissue that results from radiation damage to normal lung. Trials comparing radical radiotherapy with surgery in otherwise operable patients were performed more than 30 years ago. Initial results suggested that radical radiotherapy was the more effective treatment [125], although subsequent studies have not supported this and the place of surgery in these treatments is well established [126]. Patients who have stage IIIB (inoperable) disease have a much poorer outlook but may benefit from radical radiotherapy provided that their disease is limited to one hemithorax and can thus be encompassed by the radiotherapy field. This type of treatment is prolonged and requires the patient's performance status to be good; it is these fitter patients who seem to benefit most from this form of treatment.

A variety of techniques are employed in the delivery of radical radiotherapy, making comparison between reported studies difficult. The identification of those areas to be treated is determined from conventional chest radiographs and bronchoscopic findings. CT of the chest gives a much more precise location of the tumour, especially in the anteroposterior plane where lateral films may be difficult to interpret [127]. It is routine practice for the treatment field to include the primary tumour mass, ipsilateral and contralateral hilar lymph nodes and the mediastinum. Ipsilateral supraclavicular nodes may also be included and this is always the case in upper lobe tumours [128]. A dose-metric compromise has to be reached between delivery of a tumoricidal dose to this large area and the avoidance of injury to normal tissues, including the spinal cord, larynx and oesophagus.

In addition to planning the treatment field, the further important variables that have to be determined are the total dose of radiation, the number of fractions in which it is given and the duration of the course. In general, doses of 50–60 Gy over a period of 4–6 weeks are used. Trials from various centres using different scheduling techniques have demonstrated that survival is related to the dose of

**Table 41.7** Units of absorbed radiation.

1 joule/kg	=	1 gray (Gy)
1 Gy	=	100 rad (old units)
1 cGy (centigray)	=	1 rad

radiotherapy given. It has also been shown that small numbers of large fractions are less effective in controlling local tumour in the chest than large numbers of small fractions, even though the total dose remains the same [128]. Some workers have preferred split-course therapy, in which the same total dose is given in two half-dose courses with a 'rest period' of about 4 weeks between them, and have claimed similar results to continuous treatment [129]. Split-course treatment carries the added advantages of initial palliation due to tumour shrinkage with mild side-effects and a chance for further assessment of extrathoracic spread before the second course of treatment. This may allow the avoidance of unnecessary radical irradiation in patients with rapidly progressive disease. The argument against this form of therapy is that the design of treatment does not allow for initial local control, which could therefore deny an otherwise curable patient long survival.

The survival results of radical radiotherapy in inoperable patients are generally disappointing. Many authors report good 1-year survival figures (30–60%) but 5-year survival rarely exceeds 20% [129–131]. The subset of patients with stage I disease have a better outcome, some authors reporting up to 40% survival at 5 years [132,133]. Several factors make the results of radical radiotherapy difficult to evaluate. Firstly, the populations studied are not homogeneous as different cell types are usually lumped together as non-small-cell tumours. Also staging procedures differ within studies and by definition only inoperable patients are included. Patient survival time often reflects the spread of tumour beyond the radiotherapy field prior to treatment and need not indicate the success or failure of the local treatment. Lastly, radiotherapy itself may cause radiographic changes in normal lung that make the detection of local recurrence difficult to monitor. Despite this, the similarity of survival figures reported from various studies is striking and perhaps the most useful benchmark in a form of treatment where prolonged survival is the aim.

An interesting recent development in the scheduling of radical radiotherapy has taken into account evidence from cell kinetic studies that tumours may repopulate in the standard intervals between treatments. A regimen of continuous hyperfractionated accelerated radiotherapy (CHART) has been developed where treatment is given three times daily at intervals of 6 h for 12 consecutive days, including the weekend [134]. Although initial reports suggest that this may be a toxic regimen [135], the schedule has been modified and initial survival and local control results have been impressive [136]. CHART treatment was compared with conventional radical radiotherapy (60 Gy in 30 fractions over 6 weeks) in a randomized trial in patients with locally advanced non-small-cell lung cancer [137]. In the CHART group, there was a significant

improvement in survival at 2 years (29% vs. 20%), especially in patients with squamous histology (33% vs. 19%). However more severe dysphagia (19% vs. 3%) was seen in the first 3 months with this treatment.

*Palliative treatment*

The majority of patients with non-small-cell lung cancer who have extrathoracic metastases die within 6 months of diagnosis, and when radiotherapy is used in these patients its only aim is to relieve distressing symptoms (Table 41.8). Since this may be achieved by restraining tumour growth rather than by attempting to eradicate it totally, lower doses of radiation are generally used. Many fractionation schemes are practised throughout the UK [138], usually with a total dose of 20–30 Gy given in up to 10 fractions. Randomized controlled trials carried out by the Medical Research Council (MRC) have shown that, for fit patients, two treatments of 8.5 Gy 7 days apart are of equal efficacy to 10 daily treatments of 3 Gy [139]. In patients with poor performance status, a similar study showed that one treatment of 10 Gy is as effective as two treatments of 8.5 Gy in palliating symptoms [140].

Treatable symptoms due to intrathoracic disease, including haemoptysis, may be relieved in over 80% of cases [139], distressing cough in about 60% [139,141] and breathlessness due to bronchial obstruction in 60% [139]. However, areas of atelectasis are not re-expanded in more than one-quarter of patients [128], and dyspnoea due to lymphangitis carcinomatosa is also unrelieved. Well-localized pain due to chest wall or rib involvement responds in over 70% of patients [139,141], although more diffuse chest discomfort is often not responsive. Obstruction of the SVC is reported to be relieved in 60–86% of cases [142] and dysphagia due to oesophageal compression by nodes responds in a similar proportion of patients.

Brain metastases are nearly always multiple, and symptomatic relief may be achieved in a significant group of patients by total brain irradiation using a 30-Gy dose given as 10 fractions over 2 weeks [143]. However, improvements may be small and dense neurological deficit rarely responds. The median survival time for untreated patients with cerebral metastases is about 3 months and therefore the fractionation scheme should be

**Table 41.8** Palliative radiotherapy for distressing symptoms.

Haemoptysis
Pain: bony, chest wall, nerve root
Cough
Dyspnoea due to large bronchus obstruction
Mediastinal compression: obstruction of superior vena cava
Symptoms due to intracranial metastases
Symptoms due to spinal cord compression

as short as possible. The Royal College of Radiologists in a randomized controlled trial of patients with cerebral metastases due to various primaries showed that 12Gy in two fractions was as useful as 30Gy in 10 fractions. Median survival was 7 days longer in the second group (84 vs. 77 days), who required 8 days more treatment [144]. Dexamethasone, given initially in a dose of 16mg daily, may also produce temporary relief by reducing intracranial pressure. Spinal cord compression due to tumour is a particularly distressing complication. Prompt treatment is required to prevent permanent neurological damage, which at worst may result in paraplegia with a sensory deficit and loss of sphincter control. In this emergency situation corticosteroids should be given and, if neurosurgery is not advised, urgent palliative radiotherapy is indicated. There is still debate about the optimal treatment schedule [145]. The spinal level involved may be indicated by clinical features and confirmed more precisely by plain radiography, CT and MRI.

Other extrathoracic metastatic disease that responds to palliative radiotherapy includes bony deposits, in which pain may be relieved in the vast majority of cases, and cervical lymph node enlargement. Radiotherapy is of no value in relieving systemic symptoms, such as malaise, anorexia or weight loss, nor can it reverse a recurrent laryngeal or other frank nerve palsy. The response of the paraneoplastic syndromes (see below) to radiotherapy is variable and unpredictable.

### *Side-effects*

Side-effects tend to be dose-related and are therefore much more common in patients undergoing radical treatment. Since the aim of palliative radiotherapy is to relieve the patient's symptoms, any side-effects should be kept to a minimum. Cutaneous erythema is seen with large doses of radiotherapy but is not a serious problem. There may also be a general feeling of weakness and malaise. The patient should be warned to expect dysphagia, which is due to oesophagitis. This occurs after about 2 weeks of treatment and usually subsides spontaneously or with local anaesthetic preparations.

Radiation pneumonitis may occur following radical radiotherapy, the radiographic changes becoming evident 2–6 months after the completion of treatment. The changes are seen as a non-specific hazy infiltrate initially caused by inflammation but later as a result of fibrosis. The margin of the radiographic abnormality may be characteristically straight, matching the shielding around the radiotherapy portal. In the majority these changes are unaccompanied by symptoms, although 5–15% of patients may notice the insidious onset of breathlessness and a dry cough. The symptoms may respond to steroids but may be long-standing where progression to fibrosis occurs [146]. Radiation myelitis, potentially a most serious side-effect, may be

transient and self-limiting, in which case pain and paraesthesia occur about 3 months after radiotherapy only to disappear gradually over the space of a few weeks or months. These symptoms result from spinal cord vascular damage and demyelination. Fortunately, progression to complete paraplegia with loss of sphincter control is extremely unusual. It is estimated to occur in 1–5% of patients after a spinal cord dose of 50Gy in 25 fractions over 5 weeks [147]. The risk is increased in shorter courses with higher dose fractions. Clearly it is important to exclude cord compression from recurrent tumour before making this diagnosis. Radiation pericarditis may occur 3–6 months after radiotherapy in about 4% of patients and is associated with sternal discomfort, breathlessness and ECG changes [148]. The condition is self-limiting and treatment is symptomatic.

### *Endobronchial treatments*

Endobronchial techniques have evolved in the last two decades to help palliate symptoms such as haemoptysis and critical obstructions of main airways [149]. Most experience has been gained with laser therapy. A laser is an electrical device for producing an extremely powerful and narrow beam of light. Various types of laser are available and that most widely used in respiratory work is the Nd-Yag laser. The beam is transmitted endoscopically using fibreoptic techniques. The fibre can be passed down the suction channel of the fibreoptic bronchoscope and the beam is directed against tissue. Its energy evaporates moisture and coagulates blood in vessels to a depth of about 5mm. At present laser therapy remains a palliative treatment, as most tumour is beyond bronchoscopic view and therefore beyond the reach of the laser. Its use is confined to symptomatic relief by debulking proximal endobronchial or tracheal tumour in the treatment of dyspnoea and the coagulation of vessels in order to relieve haemoptysis. However, results from laser therapy do not add much to standard palliative radiotherapy.

Modern endobronchial radiotherapy techniques deliver high-dose irradiation to the tumour via a catheter positioned next to the tumour at bronchoscopy. Treatment takes about 10–15min and can relieve the symptoms of bronchial obstruction caused by tumour or of extraluminal pressure caused by nodes. Unfortunately, secondary haemorrhage appears to be an important complication of the procedure and studies comparing endobronchial radiotherapy with standard techniques have not yet been published.

Photodynamic therapy involves the intravenous administration of a light-sensitive drug (a haematoporphyrin derivative) that has an affinity for malignant tissue and is activated by laser light delivered at bronchoscopy. This produces necrosis of tumours in animals but its use in patients is not yet established. Another problem with

these new techniques is that they are only available in a few centres in most countries.

### Chemotherapy

The main limitation to the effectiveness of surgery and radiotherapy in patients with non-small-cell lung cancer is that evidence of metastatic spread at presentation may prevent treatment or that treatment may fail because of recurrent disease commonly occurring at distant sites. There is a clear need for 'systemic' treatment for the vast majority of patients and this has inevitably led to trials of cytotoxic drugs. Unfortunately, while chemotherapy is the mainstay of treatment of small-cell carcinoma of the lung, non-small-cell tumours are relatively resistant to the drugs currently available. Single-agent drugs have modest activity in terms of objective response rates (Table 41.9). Some authors have claimed prolonged survival for patients who respond compared with 'non-responders'. However, for such an approach to be valid, both groups must have the same prognosis with no treatment and this often cannot be assumed. Moreover, these drugs, either singly or in combination, are capable of considerable toxicity and the price paid in terms of quality of life for modest survival benefit has rarely been measured. Trials comparing chemotherapy with a control group of best supportive care have only recently appeared. Most have shown a modest survival advantage to chemotherapy treatment, although no study has accurately measured quality of life and therefore the effect of treatment on palliation of symptoms is not yet available. In a major meta-analysis published in 1995 [150], the Non-Small Cell Lung Cancer Collaborative Group analysed data published from 11 trials involving 1190 patients. Despite considerable statistical heterogeneity, the results suggested that the use of alkylating agents was detrimental to survival compared with best supportive care but that cisplatin-based regimens conferred benefits. A reduction in the risk of death of 27% was seen, equivalent to an absolute improvement in survival of 10% at 1 year. Although this may sound impressive, the overall increase in median survival was only 6 weeks. No measurements of the toxicity of the treat-

ment were performed. Many enthusiasts are keen to extrapolate these findings to the millions of people worldwide who have this disease [151] while others, worried about toxicity with such little benefit, sound a note of caution [152]. Well-designed clinical studies examining the place of chemotherapy in the management of non-small-cell lung cancer are required. It may well be that chemotherapy has a place in a multimodality approach to the disease and future studies should consider this role for chemotherapy.

### Combined modality treatment

#### *Surgery and radiotherapy*

The combination of radiotherapy and surgery was first reported in the early 1950s for tumours that were originally believed to be inoperable but which were subsequently resected after initial radiotherapy and tumour shrinkage [153]. However, no clear survival advantage has ever been shown for this scheduling of radiotherapy and surgery [154], and the concept of preoperative radiotherapy has largely been abandoned. The exception to this is with superior sulcus tumours (see below).

Compared with surgery alone, the use of *postoperative* radiotherapy for patients with N1 and N2 disease has been demonstrated to improve local control within the chest [155], and one study [156] has also shown a statistically significant survival benefit. However the exact effect of postoperative radiotherapy on survival has been questioned by a meta-analysis of nine trials showing worse survival in irradiated patients in the first 3 months [157]. This difference may be related to radiotherapy techniques (cobalt source vs. linear accelerator). It is common practice for thoracic surgeons to refer patients for postoperative radiotherapy when they know they have left disease in the chest postoperatively. These patients do particularly badly, and radiotherapy does not improve their survival.

#### *Surgery and chemotherapy*

A retrospective review performed by the Lung Cancer Study Group of the pattern of recurrences in 771 patients undergoing surgery showed that 70% initially recurred outside the chest, presumably from occult distant metastases present at the time of surgical resection of the primary tumour [124]. This has led to interest in combining good local control (surgical resection) with systemic treatment (chemotherapy) [158]. In the past chemotherapy was given postoperatively (adjuvant therapy). More recently, encouraging results have been obtained from the use of chemotherapy given before the operation (neoadjuvant) [159].

The meta-analysis conducted by the Non-Small Cell

**Table 41.9** Activity of single-agent drugs in non-small-cell lung cancer.

Drug	Response rate (%)
Ifosfamide	26
Cisplatin	21
Mitomycin	20
Vindesine	18
Doxorubicin	13
Carboplatin	11
Etoposide	9

Lung Cancer Collaborative Group [150] examined 14 trials involving a total of 4357 patients that compared surgery alone with surgery plus postoperative chemotherapy. The results are very similar to those quoted above for surgery and radiotherapy. The earlier trials that used alkylating agents showed better survival in the patients treated with surgery alone, i.e. the use of this kind of postoperative chemotherapy was actually hazardous to the patient. However, for regimens containing cisplatin there was a survival advantage for postoperative treatment. This amounted to a 13% reduction in the risk of death, with an absolute benefit from chemotherapy of 3% at 2 years and 5% at 5 years. These results are encouraging, although postoperative chemotherapy is not routine practice at present and further good clinical trials are required to confirm the suggestion of any such benefit.

The results of surgical treatment on stage IIIA patients are disappointing, with 5-year survival usually less than 30%. A number of reports have described the use of chemotherapy given prior to surgery [160,161]. Most have shown a good response to therapy and some increased resectability. In 1994 the first two randomized studies comparing neoadjuvant chemotherapy plus surgery with surgery alone appeared [162,163]. Both were small studies but appeared to show a significant benefit for neoadjuvant treatment. Roth and colleagues [162] entered 60 patients thought to have resectable stage IIIA disease; 28 patients were randomized to receive preoperative chemotherapy with cyclophosphamide, etoposide and cisplatin every 4 weeks for a total of three cycles. Patients who responded to chemotherapy were given three cycles after surgery. The objective response rate to chemotherapy was 35% including one complete response. Only 15% progressed while receiving chemotherapy. The resectability rate did not differ significantly between the two groups. Only 39% of patients in the chemotherapy group and 31% in the surgery alone group achieved complete resection. The estimated median survival in the chemotherapy group was 64 months compared with 11 months for surgery alone. In a similar study from Spain [163], 30 patients at a similar stage received mitomycin, ifosfamide and cisplatin prior to surgery. An identical number had an operation alone. Both groups received mediastinal radiotherapy following surgery. A higher proportion of patients had a complete resection compared with the first study. Median overall survival in patients receiving surgery and radiotherapy alone was 8 months compared with 26 months for the group receiving chemotherapy in addition. This trial has provoked a lot of comment. Patients in the control group did very poorly, none of the 30 patients surviving more than 20 months. The trials are small and larger studies are required to see whether this is an appropriate use of chemotherapy in this disease. Two interesting points arise: firstly, patients did not become inoperable while receiving chemotherapy for a number of weeks

prior to surgery and, secondly, the Spanish group identified the *K-ras* oncogene as a significant prognostic indicator in resected specimens. It is possible that in the future the use of this marker may be helpful in identifying which patients require adjuvant therapy [164].

### *Radiotherapy and chemotherapy*

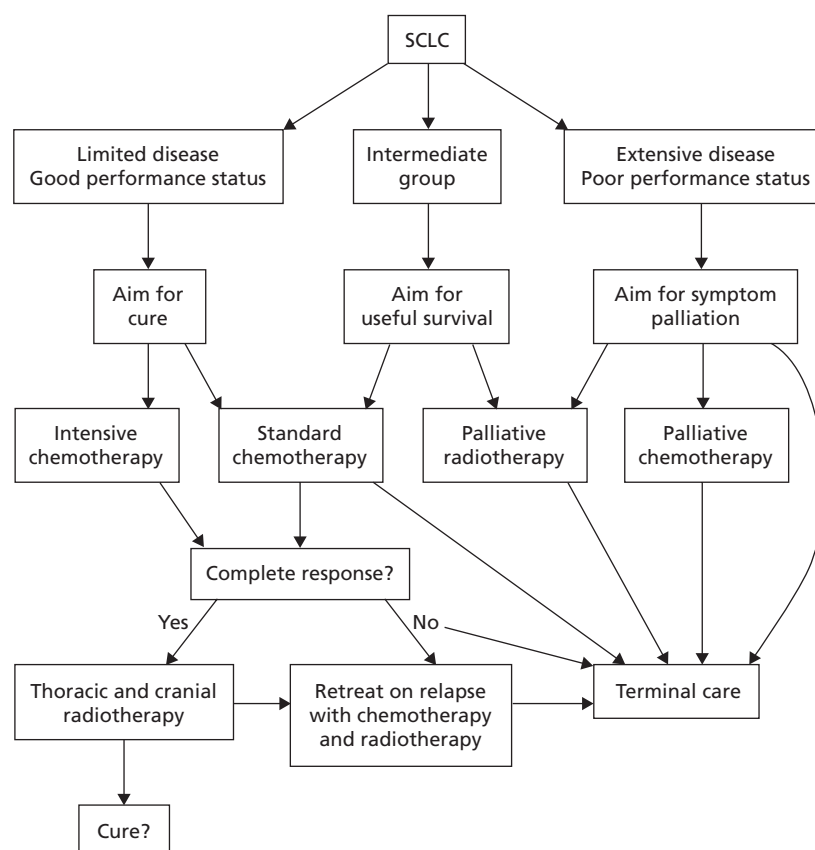

The aim of combined chemotherapy and radiotherapy is to optimize local control and to control distant metastases. In general, studies comparing radical radiotherapy alone with radiotherapy and chemotherapy have been performed in inoperable patients who have a poor prognosis. In the 1995 meta-analysis of chemotherapy [150], 22 trials involving 3033 patients were assessed. There was a definite benefit for combined therapy compared with radiation therapy alone. Cisplatin-containing regimens gave an absolute benefit of 4% at 2 years and 2% at 5 years. The optimal sequence of chemotherapy before or during radiotherapy is not known. There is evidence that platinum-based chemotherapy before radiotherapy gives a modest survival advantage, possibly in its role in controlling micrometastases, and that concurrent treatment can improve local control [165]. As with most combinations involving chemotherapy, there would appear to be more unanswered questions than answers and further randomized clinical trials are required [166].

### **Small-cell lung cancer**

Of all patients with bronchial carcinoma, 25% have small-cell tumours. These lesions grow more aggressively and patients usually present with a short history and evidence of metastases. As explained above, the disease is usually staged in terms of limited and extensive groups. Without treatment the median survival for patients with limited disease is 6–8 weeks and patients with extensive disease fare even worse [167]. At presentation more than 70% of patients have extensive disease. An outline for the management of patients with small-cell tumours is illustrated in Fig. 41.20.

### **Chemotherapy**

Unlike non-small-cell lung cancer, small-cell tumours have been found to be more sensitive to chemotherapy and this is now the accepted modality of treatment for most patients with the disease [167,168]. Many drugs have been found to have activity against this tumour, although if used singly their duration of action is brief with minimal impact on long-term survival. Responses in the range of 15–40% are seen with drugs such as cyclophosphamide, doxorubicin, vincristine, cisplatin, ifosfamide and etoposide when given alone, but fewer than 5% of patients gain a complete response [168]. Not surprisingly, when agents

**Fig. 41.20** Management of patients with small-cell carcinoma (SCLC, small-cell lung cancer).

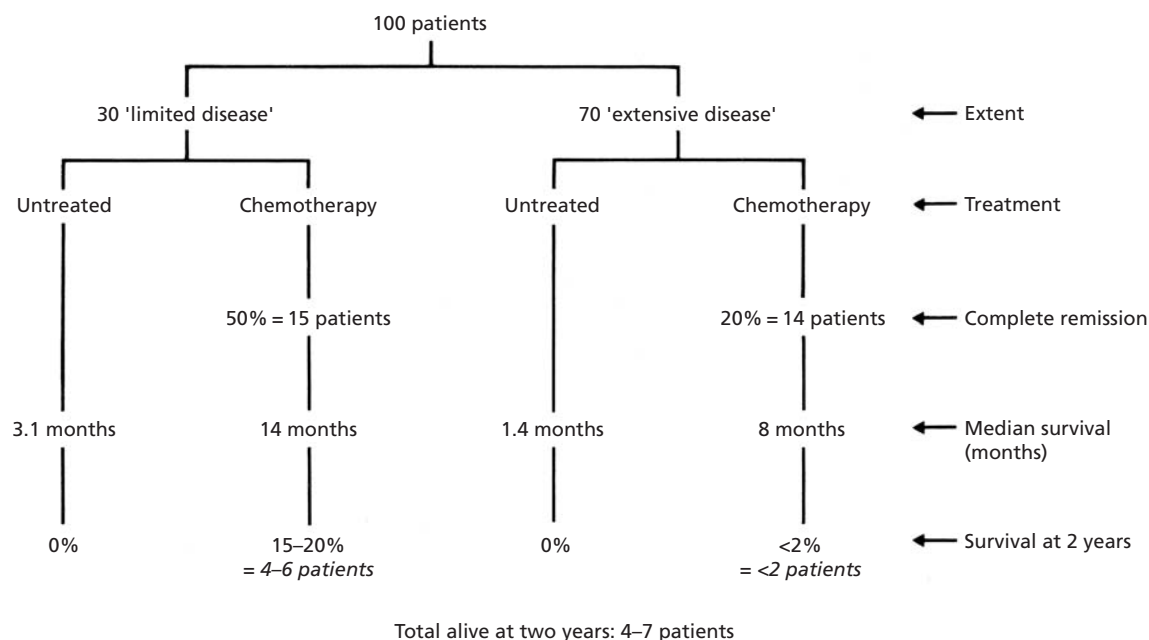

are added together and given as combination treatments the results are more encouraging. In the last two decades combination chemotherapy has improved the prognosis significantly. The median survival time in patients with limited disease is now 14–16 months and in those with extensive disease 8–10 months. The disease may show an objective response (partial and complete) to therapy in up to 90% of patients treated, and those who do respond live longer than those who do not. Drug regimens that have been well used and which have predictable results include cyclophosphamide/doxorubicin/vincristine, doxorubicin/cyclophosphamide/etoposide and cisplatin/etoposide. However, Fig. 41.21 shows the poor survival even in patients who have an apparent complete response to chemotherapy. Of 100 patients with small-cell lung cancer treated with combination chemotherapy, perhaps half a dozen survive for over 2 years, this number representing 15–20% of those with limited disease and less than 2% of those with extensive disease [169].

It is conventional to administer these combination drug regimens to the patient every 3–4 weeks. This can largely be done on an outpatient basis. Treatment with platinum requires careful hydration and antiemetic therapy and should only be given in specialized units. Patients should be assessed for response to treatment after a minimum of two or three cycles unless the disease is obviously

progressive or the patient cannot tolerate the treatment. Oncologists often measure activity of treatment in terms of response rates. An objective response to therapy may be either partial or complete. In a partial response, shrinkage of the tumour by at least 50% in a measurable diameter must have occurred. A partial response is not recorded if tumour at another site is progressing. It is clear that there must be inaccuracies in this form of assessment. Measuring a shadow on a chest film gives definitive data but it is often not known whether the radiographic opacity is due to tumour or perhaps to atelectasis or consolidation behind the tumour. Clearly, opening up a small endobronchial lesion may cause dramatic 'improvement' on a chest film when in fact the response of the tumour may be minimal. Complete responses, seen in approximately half the patients with limited disease and one-quarter of the patients with extensive disease [168], are defined as the total removal of all tumour as evaluated by physical examination, radiography, scanning or bronchoscopy.

Although the early results of drug treatment in small-cell carcinoma were very promising, the survival of patients with 'conventional' treatment has reached a plateau with little change over the last decade [170]. A variety of different therapeutic manoeuvres have been tried in order to improve this situation.

**Fig. 41.21** Probable results in 100 patients with small-cell lung cancer.

### High-dose chemotherapy

It is known that combinations of two and three drugs have much more activity than single-drug therapy in gaining a remission and it is likely therefore that a definite dose–response relationship exists in the treatment of this disease. Several strategies have been tried to increase the initial dose of induction chemotherapy in order to try to prevent later relapses. The main problem with increasing the intensity of drug treatment is that the toxicity experienced by the patient is also increased. In a typical early study of high-dose chemotherapy, fit patients with limited disease were prospectively randomized to either a double dose ( $1.5\text{g}/\text{m}^2$ ) or a standard dose ( $0.75\text{g}/\text{m}^2$ ) of cyclophosphamide in a regimen also containing methotrexate and lomustine at conventional doses. The high-dose group had a significantly increased median survival rate of 56 weeks compared with 42 weeks for standard therapy. This was at the expense of 'a life-threatening complication' rate of 53% compared with 7% and a drug-related death rate of 4% vs. 1% [171]. The toxicity of this treatment is clearly unacceptable for the small benefit in survival.

The principal drug-related toxicity that threatens life is myelosuppression. Two strategies have been developed to try to overcome this problem. Autologous bone marrow transplantation [172] involves taking marrow from a patient prior to chemotherapy, giving high doses of chemotherapy that would normally cause complete marrow failure, and managing this by replacement with

the patient's own harvested bone marrow. High doses of chemotherapy can be given with this technique, although complete eradication of the disease rarely occurs. One potential problem with this method is that malignant cells may be harvested as well as normal marrow cells; thus when marrow cells are reinjected after chemotherapy, the patient also receives untreated cancer cells. Attempts have been made to overcome this by 'cleansing' the bone marrow after harvesting. The other strategy involves the use of haematopoietic growth factors that can stimulate normal haematopoiesis [173]. Granulocyte colony-stimulating factor can be produced by recombinant DNA techniques and allows clinicians to increase the production of bone marrow cells by patients after myelotoxic chemotherapy. The results of randomized studies using this technique to allow higher doses of chemotherapy are awaited.

In intensive regimens it is important to be aware that there may well be a selection bias, with patients whose general condition is poor being excluded as they would be unable to tolerate the rigours of high-dose chemotherapy. Valid comparisons can only be drawn if the performance status, the extent and size of the tumour, and the age of the patient are known.

### Scheduling

Several randomized trials have attempted to determine the minimum number of courses of chemotherapy that can be given without compromising survival, aiming to minimize toxicity and improve the quality of life of the patient. The MRC reported a trial in 265 patients who had responded to induction chemotherapy (six courses of

etoposide, cyclophosphamide, methotrexate and vincristine). Patients were then randomized to receive a further six courses of the same chemotherapy (maintenance chemotherapy) or no further treatment until relapse. No overall survival advantage was seen for maintenance chemotherapy [174]. The same researchers have compared six courses of the same treatment to three courses in a randomized study of 458 patients [175]. There appeared to be a marginal survival advantage for the six-course regimen.

In an interesting study reported by the London Lung Cancer Group [176], 616 patients were randomized to receive either four or eight courses of chemotherapy (etoposide, cyclophosphamide and vincristine) and at relapse to receive either symptomatic treatment or further chemotherapy with new agents (methotrexate and doxorubicin). The results showed that patients receiving only four courses of chemotherapy and then symptomatic treatment at relapse had a much poorer median survival compared with the other three treatment groups (30 weeks vs. 39–42 weeks). There was no advantage to relapse chemotherapy in the group given eight courses initially.

The concept of introducing at relapse further combinations of new drugs to which the residual tumour cells would not be resistant has been tried before. Many studies have compared alternating (crossover) regimens but consistent benefit in terms of increased median survival has not been shown. As with high-dose induction chemotherapy, this strategy has largely been abandoned. In summary therefore it seems that patients given chemotherapy for small-cell lung cancer should receive, if possible, no less than four but no more than six courses of induction therapy. Maintenance chemotherapy is of no value but retreatment on relapse is worth while.

### Complications

The main agents currently used in combination chemotherapy for small-cell lung cancer may produce significant toxicity. Myelosuppression may lead to bleeding problems and infections. Febrile episodes in neutropenic patients are associated with infection in about 60% of cases [177,178] and require immediate broad-spectrum antibiotic treatment. Likely pathogens include *Staphylococcus aureus*, *Pseudomonas aeruginosa* and *Escherichia coli*. Although treatment may be modified in the light of subsequent microbiological culture, it is inadvisable to withhold antibiotics pending these results [179]. Nausea and vomiting commonly accompany treatment with cytotoxic drugs, especially platinum compounds. Pharmacological techniques have been developed to counteract this, with the use of intravenous antiemetics such as metoclopramide and ondansetron. Patients often express fears of alopecia. However this is transient and is best managed by early counselling and an appropriate wig.

In general it is clear that chemotherapy is best given by experts. Oncology units are obviously well geared to support patients both physically and psychologically through chemotherapy, and most of the clinical trials of treatment in this condition are conducted by oncologists rather than respiratory physicians. However, patients with lung cancer are almost always referred to respiratory physicians who are keen to give chemotherapy themselves. Once again, a team approach involving interested clinicians would appear to be in the patient's best interests.

### Palliative effects

Patients with small-cell lung cancer have a dreadful prognosis if untreated and in general the results of chemotherapy in terms of long-term prolongation of survival are poor. Some clinicians take the view that the use of chemotherapy is not always justified because of toxicity and the adverse effects of treatment. For many years there was a feeling that it was cruel to inflict treatment on old and ill patients and that any prolongation in life would be of poor quality. Is this protective attitude by clinicians reasonable or does active treatment have any palliative benefit? In the MRC trial comparing three and six courses of chemotherapy [175], effects of the treatment on the patient's symptoms were recorded. Good relief of local symptoms was seen, the vast majority of patients reporting palliation and, in many, disappearance of symptoms. Also, systemic problems such as anorexia were greatly improved, a feature not seen with local treatment such as radiotherapy.

Some clinicians believe that patients who are well at diagnosis should be left until they develop symptoms, which should then be palliated. This approach was compared with standard immediate treatment in an MRC trial [180]. Patients given immediate treatment had much better survival and, although adverse effects of treatment were more common in this group, other aspects of quality of life as recorded by clinicians were better. Other authors have also shown that patients who respond to chemotherapy have improvement in symptoms and quality of life [176], and it can be concluded that if patients are fit to have chemotherapy it should not be withheld since good control of disease and good palliation go together.

A more difficult decision can be whether to treat patients who have extensive disease and poor performance status. Obviously it is important that chemotherapy is not given to a patient for whom there is no realistic prospect of useful palliation or improvement in the quality of life. Recently, many groups have been investigating the use of simple more 'gentle' chemotherapy regimens that have minor side-effects but adequate anti-tumour activity. This would allow outpatient treatment, with modest improvement in survival and good palliation

of symptoms without the cost, toxicity and need for in-patient care of more intensive regimens. Oral treatment with etoposide often forms the basis of these regimens [181]. Pharmacokinetic studies with this drug have shown that it is much more active when given in a chronic schedule, which makes its oral administration more attractive than intravenous use. Its safety and efficacy have been demonstrated in a large phase II trial in elderly patients [182]. Etoposide capsules were administered for 5 days to a total dose of 800 mg/m<sup>2</sup>. A response rate in excess of 70% and a median survival of 9.5 months was seen, results comparable with the efficacy of more toxic and complicated combination chemotherapy regimens. Haematological and gastrointestinal toxicities were minimal and admissions to hospital for treatment related to toxicity were seldom necessary. However when oral etoposide was compared to 'standard' combination intravenous chemotherapy in a randomized trial it was found to be less effective in terms of survival [183]. Its place in the management of this disease is thus uncertain as it appears to be reasonably tolerated but relatively 'weak' therapy.

### Radiotherapy

As with chemotherapy, small-cell tumours are in general more radiosensitive than non-small-cell varieties. However, the precise role for radiotherapy in small-cell tumours remains undefined. It may fulfil a useful palliative role in the treatment of distressing symptoms such as haemoptysis, localized pain and intractable cough, as well as those symptoms arising from CNS metastases, bone secondaries and obstruction of the SVC. What is the place of radiotherapy in patients with small-cell carcinoma in whom the ultimate yet remote objective is to cure or at least further prolong survival significantly?

### Primary tumour control

It is clearly evident that radiotherapy, like surgery, is a local treatment and is therefore unlikely to be successful in disease that disseminates widely at an early stage. Since chemotherapy has the theoretical potential to treat disseminated disease and radiotherapy that of augmenting any effect the drug treatment has on more bulky localized intrathoracic disease, many centres have investigated the place of thoracic radiotherapy as an adjunct to chemotherapy. The primary site is by far the most common location for disease to relapse after failure of chemotherapy and therefore it is to be expected that combining radiotherapy with chemotherapy might improve survival. Almost all studies comparing chemotherapy and thoracic radiotherapy with chemotherapy alone have shown a reduction in local recurrence rate, from an average of 80% to about 30%, although few have shown much impact on survival [184–187]. It has taken two large meta-analyses [188,189]

involving more than 2000 patients in more than a dozen randomized trials to show any impact on survival for the addition of radiotherapy to combination chemotherapy in patients with limited small-cell lung cancer. More modern chemotherapeutic regimens using platinum drugs have not been reported or included in these meta-analyses [190] nor has the optimal dose and scheduling of radiotherapy been established. Reports from a French study [137,191], where dose escalation was performed, have shown that at least 40 Gy are required for a clinical response but that toxicity with this kind of treatment is common. The scheduling effect is also important since it is known that the therapeutic ratio of radiotherapy improves with division of the total dose into fractions (see above). A larger-than-standard fraction dose (>2 Gy) produces a larger kill of tumour cells but causes an increased risk of late effects to normal tissues. Dividing the total daily dose into smaller doses (hyperfractionation) improves this therapeutic index. Accelerated fractionation allows for frequent treatments in a shorter time span. The interval between treatments allows some repair of the damage to both cancer and normal tissues. The theory behind hyperfractionation and accelerated schedules is to optimize the effects of radiotherapy on tumour cells while allowing normal cells to recover. The precise sequencing of radiotherapy with chemotherapy is important, although an optimal schedule could not be discerned from the recent meta-analyses [188,189]. Two studies looking at early radiotherapy or late treatment, i.e. at the end of chemotherapy, have shown conflicting results [192,193].

It is generally accepted that if patients are to be submitted to thoracic radiotherapy as an adjunct to chemotherapy they should have limited disease at presentation, show a complete regression with chemotherapy or have local symptoms attributable to the disease. The optimal dose, fractionation and timing in relation to chemotherapy are undetermined and combined modality treatment may produce substantial toxicity [194].

### Prophylactic cranial irradiation

The use of prophylactic cranial irradiation (PCI) in order to prevent the emergence of intracranial metastases is controversial. The reasons for its use are (i) the brain is a common site for spread of small-cell carcinoma, (ii) cytotoxic drugs in general do not cross the blood–brain barrier and (iii) the incidence of brain metastases increases as survival is prolonged by chemotherapy. In a meta-analysis of 11 studies, Pedersen [195] calculated that about 10% had CNS metastases at diagnosis of small-cell lung cancer, while a further 20% developed these during therapy. At autopsy the frequency was found to be approximately 50%. The small group of patients surviving for more than 2 years after diagnosis has been shown to have a probability of developing brain metastases of 50–80% [195,196]. Brain

metastases are associated with considerable morbidity for the patient and distress for the relatives. Patients are often hospitalized [197] and their survival is short. Irradiation of the brain does not of course prevent new metastases in a relapsed patient and therefore strictly speaking the term 'prophylactic' is inappropriate.

By 1995, 11 trials that randomized patients into groups receiving and not receiving PCI had been published [198]. All showed a significant reduction in the CNS relapse rate, from approximately 25% to 5%, but none showed a significant survival advantage favouring PCI. In the largest recorded study [199], in which 219 patients with limited disease were randomized to either PCI with 30Gy over 10 fractions ( $n=107$ ) or no brain therapy ( $n=112$ ), the CNS relapse rate was reduced from 20% to 5% by PCI but there was no impact on survival.

The adverse effects of PCI may also be significant. An acute organic syndrome, with memory loss, confusion and additional neurological deficits, can be seen 6–8 weeks after treatment in a small proportion of patients [200]. Late neurological toxicity has been reported in retrospective series of long-term survivors who have received PCI [201]. There appears to be a link between these effects and the timing and dose of radiotherapy. In summary therefore PCI is not advised as routine treatment and should only be given to patients with limited stage disease who are in complete remission following chemotherapy [202].

However, palliative cranial irradiation is often helpful in relieving distressing symptoms due to cerebral metastases. Dexamethasone is also useful in these patients and their response to this treatment is often taken as a guide to whether cranial irradiation should be attempted. The results from patients who have been treated show an intracranial response rate of approximately 70%, with 40% having a clinically complete remission [198]. Patients presenting with intracranial metastases from small-cell lung cancer have been shown to respond to systemic chemotherapy and this should still be part of the primary treatment [203].

## Surgery

The early MRC studies on the treatment of small-cell carcinoma compared surgery unfavourably with radiotherapy and found no long-term survivors after operative treatment [204]. This led to a widespread belief that small-cell lung cancer was a 'systemic' disease regardless of clinical stage at presentation and that surgery was contraindicated in all patients. The early promise of chemotherapy in the 1970s led to its emergence as the standard form of treatment and physicians largely forsook surgery as a treatment option. However, this was not true of those many thoracic surgeons who had seen cures following operation. In the last decade chemotherapy results have

reached a plateau (see above) and manipulations of combination chemotherapy and radiotherapy seem to have had little or no further impact on survival. These observations, coupled with reports of occasional long-term survival following surgical treatment, has led to questioning of the dogma that small-cell carcinomas are inoperable. The Veterans Administration Surgical Oncology Group entered over 2000 patients into a study to evaluate the role of adjuvant chemotherapy in patients with resected non-small-cell lung cancer [205]. It was found that 148 patients with early-stage small-cell lung cancer were inadvertently included. Review of these patients showed remarkable 5-year survival rates: patients with T1N0 tumours had 60% survival, those with T2N0 27.9% and those with T1N1 31.3%. The overall 5-year survival rate, which included patients with T3 and N2 disease, was 23%.

Other workers have shown that when solitary pulmonary nodules removed from asymptomatic patients were subsequently found to be small-cell carcinomas, and when no obvious lymph node metastases were present, the 5-year survival rate was about 36% [206]. Although fewer than 5% of patients with small-cell carcinoma are found to have stage I disease after extensive staging, those that do so comprise a small subgroup that may benefit from surgical resection.

Patients with limited small-cell lung cancer treated with chemotherapy and thoracic radiotherapy have a high incidence of local recurrence, and this has led a number of investigators to re-explore the role of surgery in combination with other treatment in limited small-cell lung cancer [207,208]. Three uncontrolled studies in small groups of patients with limited small-cell lung cancer treated with preoperative chemotherapy followed by attempted surgical resection have shown that combined modality therapy is possible. All studies showed a high local control rate and, perhaps more interestingly, a high incidence of mixed histology or a conversion to non-small-cell histology following chemotherapy [208–210]. This presumably reflects the emergence of a chemoresistant clone of cells in mixed tumours and explains the poor eventual results of chemotherapy.

The largest study that has evaluated the role of surgery in small-cell lung cancer was by a group from Toronto [211]; 119 patients with limited disease were treated with combined modality therapy including surgical resection. The projected 5-year survival in stage I patients was 51%, stage II 28%, stage III 19% and the overall survival was 39%. The pattern of recurrence showed good local control, with local recurrence only in 8.3%. The Lung Cancer Study Group has performed the only prospective randomized trial evaluating the role of surgery in patients with limited small-cell lung cancer [212]; patients with stage I disease were excluded. All patients were treated with standard chemotherapy and were then randomized to receive radiotherapy (thoracic and PCI) with or without

thoracotomy. The resectability rate was 83%, 19% had a complete pathological response and 9% of patients had no residual small-cell lung cancer but only non-small-cell lesions. The 2-year survival was 20% irrespective of whether an operation was performed.

It is appropriate in the present stage of knowledge for limited small-cell lung cancer to be further classified using the TNM system and for peripheral lesions to be assessed for surgery. Mediastinoscopy should be performed even when CT is normal and the patient should probably undergo bone and brain scanning. The question of whether postoperative adjuvant chemotherapy is beneficial is at present unanswered but the reports so far show no favourable impact on survival. However, results of surgical treatment in this very select group of patients with small-cell lung cancer is certainly as good as chemotherapy alone.

**Paraneoplastic syndromes**

The term ‘paraneoplastic syndrome’ encompasses a variety of non-metastatic metabolic or neuromuscular manifestations of lung cancer [213,214]. Although such syndromes may occur with all major types of lung cancer, they are most frequently associated with small-cell carcinoma, which commonly elaborates ectopic hormones from neurosecretory granules within its cells. In healthy subjects, these peptide hormones (Table 41.10) are produced not only in neural tissue, including the hypothala-

**Table 41.10** Peptide hormones detected in small-cell lung cancer. (After Maurer [213].)

Hormone	Normal site of production
Thyrotropin releasing hormone Somatostatin	Hypothalamus
Thyrotropin Growth hormone β-Melanocyte stimulating hormone Adrenocorticotropin β-Endorphin β-Lipotropin Pro-opiomelanocortin	Anterior pituitary
Vasopressin Oxytocin VP-HNP OT-HNP	Posterior pituitary
Bombesin Neurotensin Glucagon	Gut-brain
Calcitonin	C-cells (thyroid)

mus and pituitary, but also in gut-derived tissues and are therefore sometimes referred to as gut-brain peptides. Although increasing numbers of these peptides are being detected by sensitive radioimmunoassay techniques, most of them are unassociated with gross clinical disturbances. However, a number of metabolic paraneoplastic syndromes are well recognized clinically. The mechanisms by which the paraneoplastic neuromuscular syndromes arise remain for the most part obscure. These syndromes may antedate discovery of a tumour by months or even years [215].

**Hypercalcaemia**

Malignant neoplastic disease is the most common cause of hypercalcaemia in the hospital population, accounting for about 60% of cases. Approximately 8% of patients with lung cancer are found to have hypercalcaemia and the majority of these have squamous cell carcinoma [216]. The most common cause of malignant hypercalcaemia is destruction of bone by osteolytic metastatic disease, but it may also result from the production of abnormal circulating factors by the tumour. True ectopic parathyroid hormone production is extremely rare [217], although lung cancers, especially squamous carcinoma, can produce parathyroid-like hormones that cause hypercalcaemia via increased mobilization of calcium from bones and by increased renal tubular absorption [218]. Hypercalcaemia produces polyuria, nocturia and thirst that if persistent result in dehydration, hypovolaemia and ultimately renal failure. The patient may experience malaise, weakness, anorexia, nausea, vomiting and constipation. Mental slowing, confusion, drowsiness and ultimately coma may mislead the physician into supposing that intracranial metastases are present. The symptoms may develop insidiously or so rapidly that the patient presents as a medical emergency.

In advanced or terminal malignancy, a decision not to treat hypercalcaemia may be taken with justification. However, if it is felt that the patient’s quality of life would benefit from lowering the serum calcium, then treatment should be vigorous. If there are no obvious bony metastases it can be assumed that the tumour is producing parathyroid hormone-like substance. Treatment of the primary should therefore result in biochemical improvement, and resection or radiotherapy should be planned in the usual way, first correcting the biochemical disturbance by medical means.

The mainstay of medical treatment is correction of associated dehydration with intravenous saline. Renal function should be closely monitored and adequate potassium supplementation given. Mild hypercalcaemia (<3 mmol/L) may respond to this alone but when hypercalcaemia is more severe, or does not respond to simple rehydration, a loop diuretic such as furosemide (frusemide) should be

given in addition to intravenous fluids. If hypercalcaemia persists despite these measures, agents can be used that inhibit calcium resorption from bones. Intravenous and oral bisphosphonates have an important role to play in the management of malignancy-associated hypercalcaemia and may cause fairly dramatic falls in serum calcium [219]. The cytotoxic antibiotic mithramycin is no more effective and is rarely used due to toxic effects. Oral steroids have an unreliable calcium-lowering activity in hypercalcaemia associated with bronchial carcinoma, but are often used nevertheless.

### **Syndrome of inappropriate antidiuretic hormone secretion**

When significant hyponatraemia (plasma sodium  $<120$  mmol/L) occurs in association with lung cancer, it is usually part of the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). This nearly always occurs in small-cell carcinoma, and SIADH is the most frequently encountered paraneoplastic syndrome associated with this cell type, being reported in 5–22% of patients [213]. SIADH is characterized by dilutional hyponatraemia, so that plasma sodium is low in the presence of abnormal water retention, resulting in low plasma osmolality (usually  $<260$  mosmol/kg of water). There is continued urinary loss of sodium at a level inappropriate for the plasma sodium concentration so that urine osmolality is disproportionately high, being at least twice that of plasma. The syndrome is due to uncontrolled secretion of ADH by the tumour, and the diagnosis is made by measurement of urine and plasma osmolality.

The patient may be asymptomatic or may complain of anorexia, weakness, nausea, vomiting and headache. As hyponatraemia worsens, impaired concentration with forgetfulness and confusion may develop. With a plasma sodium concentration of less than 115 mmol/L, seizures and coma may occur.

The cornerstone of treatment of SIADH is water deprivation [220], 500–750 mL of fluid being given daily in addition to the losses in the previous 24 h. This water deprivation may be unpleasant for the patient, and where compliance is difficult, or where treatment has proved unsuccessful, the antibiotic demeclocycline may be given orally [221,222]. This drug competes for ADH binding sites in the renal tubule and is given in a maintenance dose of 600–900 mg daily. It undergoes hepatic metabolism and is best avoided in patients with renal insufficiency or liver disease, otherwise nephrotoxicity may result. It may also cause a photosensitivity reaction.

As with other ectopic hormone production, treatment of the primary tumour (usually with chemotherapy) may produce a prompt response [223]. However, many chemotherapeutic agents used in the management of small-cell lung cancer, such as cyclophosphamide, vin-

cristine and cisplatin, can produce SIADH themselves [224].

### **Ectopic adrenocorticotrophin secretion**

Abnormalities of cortisol metabolism may be found in almost 50% of patients with small-cell carcinoma. Raised concentrations of immunoreactive adrenocorticotrophin (ACTH) can be detected and there is a loss of diurnal variation or failure of cortisol to suppress following dexamethasone [225,226]. Despite this, the clinical syndrome of ectopic ACTH secretion has been found to be present in only 5% of patients with small-cell carcinoma and is even less common in other cell types [213,225]. Patients do not usually develop the signs associated with Cushing's syndrome such as moon face, central obesity and cutaneous striae, presumably because the relatively short natural history of the small-cell carcinoma does not allow the development of these abnormalities. Indeed it has been shown that ectopic ACTH secretion seems to carry a poor prognosis [225].

The diagnosis is usually made when symptoms such as anorexia, mental slowing and muscle weakness, which may be profound, are associated with a hypokalaemic metabolic alkalosis due to urinary loss of potassium. The most common physical findings are oedema (83%) and proximal myopathy (61%) [227]. Progressive cutaneous pigmentation is sometimes a feature of the syndrome and results from associated  $\beta$ -melanocyte stimulating hormone production. Confirmation of the diagnosis is made by finding an elevated cortisol level that fails to fall following dexamethasone administration. Plasma ACTH assay also shows elevated levels.

The most effective treatment of this syndrome is treatment of the tumour itself. This usually takes the form of chemotherapy of small-cell carcinoma, although successful resolution has occasionally resulted from resection [228]. Inhibition of adrenal steroid synthesis with the anti-fungal agent ketoconazole has been shown to be beneficial [229], and this drug should be administered to patients with the syndrome while a response to chemotherapy is awaited.

### **Hypertrophic pulmonary osteoarthropathy**

Hypertrophic pulmonary osteoarthropathy (HPOA) is a syndrome characterized by periostitis of long bones, most commonly affecting the tibia, fibula, radius and ulna at their distal ends. The patient complains of bony pain in these involved areas, which are often hot and tender to touch, and there may be associated pain and swelling of the wrists, ankles and knee joints [230]. Clubbing of the digits is found in over 90% of cases, and is often gross [231].

The pathogenesis of the condition remains obscure but

lung cancer is by far the most common cause. Although some authors believe that HPOA is usually associated with adenocarcinoma [232], other workers have shown an equal distribution between major cell types with the exception of small-cell carcinoma [233]. HPOA is closely associated with finger clubbing and has been recorded in a variety of other malignant and non-malignant conditions associated with clubbing. It has been shown that blood flow to the calf and forearm is increased in HPOA and that this hyperaemia is directed particularly towards connective tissue and bone. The increased vascularity of subcutaneous tissues and periosteum leads to periostitis, resulting in loosely packed new bone being laid down outside the original cortex [234] and this produces the characteristic bony radiographic changes.

The mechanism by which lung cancer produces HPOA remains obscure. There is some evidence to support a role for vagally mediated afferent neural output from the tumour-bearing lung, as it was noted in the 1950s that division of the vagal branches around the hilum during unsuccessful attempts to resect lung cancer resulted in symptomatic relief, whereas 'open and shut' thoracotomy without nerve section produced no relief [235]. A number of possible pathogenic mechanisms have been put forward but none are universally accepted. When the diagnosis is suspected, radiographs of the lower ends of the radius, ulna, tibia and fibula, and of the hands are indicated. If the knees are painful, radiography of the proximal tibia and fibula and distal femoral shaft should be performed. The characteristic radiographic finding is a 1–2 mm line shadow running parallel to the cortex starting a few centimetres beyond the wrist or ankle joint and running for a variable distance along the shaft of the bone (Fig. 41.22). The active deposition of new bone along the inner aspect of the periosteum can be demonstrated on bone scans by the avid uptake of technetium in affected areas, although this investigation is seldom necessary in clinical practice.

Despite the reported success of vagotomy [235], this invasive procedure is unjustified unless thoracotomy is undertaken for an attempt to cure. In cases where successful resection of tumour is achieved, HPOA responds dramatically. Most other cases respond gratifyingly to treatment with a non-steroidal anti-inflammatory drug and corticosteroids may produce similar relief.

### Other endocrine and metabolic complications

#### Gynaecomastia

This may occasionally occur in association with lung cancer, most frequently with large-cell and adenocarcinoma types. The mechanism is thought to involve the production of human chorionic gonadotrophin by tumour cells, this substance resulting in overproduction of testicu-

**Fig. 41.22** Hand of patient with hypertrophic pulmonary osteoarthropathy showing subperiosteal new bone formation on metacarpals and phalanges.

lar oestrogen [236]. Drug-induced gynaecomastia (e.g. with spironolactone, cimetidine, digoxin) should be excluded before this physical sign is attributed to a tumour; however, when lung cancer is the cause, successful surgical resection also deals with the complication. If resection is not possible, then an antioestrogen such as tamoxifen may be effective in relieving symptoms.

#### Eosinophilia

As association between bronchial carcinoma and blood eosinophilia has been described [237]. This phenomenon, which may result from increased marrow production, prolonged eosinophil survival time or the production of an eosinophil chemotactic factor, is characterized by a high total white cell count and neutrophilia as well as eosinophilia [238]. It tends to be associated with advanced and rapidly progressive disease.

#### Non-metastatic neuromuscular syndromes

Paraneoplastic neurological syndromes have long been

recognized in lung cancer and these disorders are now thought to result partly from the cross-reaction of anti-tumour antibodies with antigens also present in neural tissue [239]. A variety of neuromuscular syndromes are recognized.

**1** A peripheral neuropathy, which may be motor, sensory or mixed, accompanied by muscle weakness and wasting with loss of tendon reflex and stocking and glove hypoaesthesia. An autonomic neuropathy has also been described that may result in postural hypotension or disturbances of gastrointestinal motility, including intestinal pseudo-obstruction (Ogilvie's syndrome) [240]. Patients with sensory neuropathy usually have small-cell lung cancer and often have high titres of antibody to the nuclear-associated HuD protein [241]. However, the pathogenesis of neural injury is uncertain [227].

**2** Neuromuscular junction and muscle syndromes include polymyositis/dermatomyositis, typified by proximal muscle weakness, pain and tenderness with a variety of systemic symptoms and a characteristic facial heliotrope rash. The myasthenic (Eaton-Lambert) syndrome is reported to occur in up to 6% of patients with small-cell lung cancer. In contrast to myasthenia gravis, the patient's muscle weakness improves with repeated efforts. The syndrome is thought to result from autoantibody-mediated functional blockade of the voltage-gated calcium channels involved in the release of acetylcholine at nerve terminals [227].

**3** Cerebellar ataxia, with nystagmus, impaired coordination and dysarthria, has been described in a small group of patients with small-cell lesions [242].

Paraneoplastic neurological syndromes associated with small-cell lung cancer often precede discovery of the underlying tumour. Apart from patients with Eaton-Lambert myasthenic syndrome, immunosuppression including plasmapheresis has not been shown to be particularly beneficial, even in patients with detectable antineural antibodies. Similarly, the neurological syndromes generally do not respond to cytotoxic chemotherapy, even when there is a gratifying antitumour effect [227].

## Special problems

### Obstruction of the SVC

Over 85% of all cases of obstruction of the SVC are caused by malignant disease. Bronchial carcinoma is responsible for over 60% of cases, about 20% being accounted for by other tumours such as lymphoma, mesothelioma and metastatic mediastinal lymphadenopathy. The few remaining cases are caused by rare benign conditions, including granulomatous disease, cryptogenic mediastinal fibrosis, intrathoracic goitre or aneurysm, or as a complication of central venous catheterization [243]. Small-cell

carcinoma is the commonest histological type of lung cancer involved and up to 10% of small-cell lesions present in this way [244]. The tumour usually compresses the vessel from without but occasionally invades its wall. Intraluminal thrombosis sometimes occurs and may be responsible for failure of treatment.

### Diagnosis

The diagnosis is usually obvious from the symptoms and signs, with swelling of the face and upper torso and distension of veins and venules across the chest, upper arms and neck. The next step is to obtain histological confirmation. Some hold the view that it is more important to initiate immediate treatment with radiotherapy before obtaining histology, but this approach has several pitfalls. Firstly, radiotherapy may be administered to a patient with a benign condition, thus subjecting the individual to the potential toxicity of treatment without any chance of benefit. Secondly, if radiotherapy is administered first it may make a subsequent histological diagnosis difficult or impossible, and in those patients whose survival is prolonged the subsequent management becomes increasingly problematical. Thirdly, if the tumour responsible is small-cell carcinoma, this responds well to chemotherapy and radiotherapy may not be required at all [244]. Obstruction of the SVC, although unpleasant, is unlikely to result in mortality but the underlying cause is and it is therefore important to determine this cause as accurately as possible. Histological diagnosis is usually obtained by bronchoscopy where a central pulmonary tumour is evident or by exploration of the mediastinum via mediastinoscopy or mediastinotomy. The risks of uncontrollable bleeding as a result of raised venous pressure proximal to the obstruction have probably been overstated and in practice routine biopsies should be performed [245]. In patients without an endobronchial lesion at bronchoscopy, mediastinotomy is almost always diagnostic and carries the potential advantage of providing larger tissue samples, which may be important in lymphoma and in more unusual causes.

CT with contrast venography may be helpful in determining the extent of the disease although usually adds little to clinical examination and chest radiography. Some radiotherapists claim to have found venography helpful in determining how far to extend the treatment field and this procedure is also required if stenting of the SVC is contemplated [246].

### Treatment

Treatment in cases due to cancer of the lung depends on whether histology is consistent with small-cell carcinoma or not. In a patient with small-cell carcinoma in whom a decision to use chemotherapy as primary treatment has

been taken, the additional use of radiotherapy appears to confer no extra benefit [244,247]. In non-small-cell carcinoma, chemotherapy has not been shown to produce any relief over and above that resulting from treatment with radiotherapy [248]. Studies with more modern drugs (e.g. cisplatin) in patients with obstruction of the SVC due to non-small-cell carcinoma have not been performed. Corticosteroids are frequently used but have not been convincingly shown to be of benefit.

Radiotherapy is the mainstay of treatment in cases due to non-small-cell lung cancer. The high initial dose of radiotherapy followed by a lower daily dose to a total of approximately 20Gy spread over 1–2 weeks is claimed to be more effective than initial low-dose treatment increased by gradual increments [248]. Symptoms usually begin to improve rapidly with signs diminishing more gradually, so that 90% of patients are free from oedema by 3 weeks. Radiotherapy in the treatment of obstruction of the SVC due to lung cancer is a palliative procedure and the ultimate prognosis depends on the cell type, the extent of the disease and the performance status. It has been reported that those who do not show a rapid response to radiotherapy die sooner than those who do, approximately 25% of patients overall surviving for 1 year [244,249]. In small-cell lung cancer, obstruction of the SVC is not in itself a poor prognostic indicator [244], and patients who relapse with obstruction of the SVC following initial chemotherapy should be treated with radiotherapy as there is a good chance of at least a partial response to both symptoms and signs.

Endovascular treatment of obstruction of the SVC has also been tried. Initial attempts using simple balloon angioplasty was occasionally successful in benign disease but recurrence rates in malignant disease are very high due to inability of the central veins to resist external compression. Since the first report of the successful placement of an intravascular stent in 1986 [250], there have been several reported series documenting the value of this technique [246,251,252]. So far its use appears to be confined to patients with malignant obstruction of the SVC who have failed to respond to conventional treatment or who require urgent relief of symptoms. Results of this form of treatment are impressive, with a primary clinical success rate in the region of 90% of patients [252]. There is no clear consensus on the need for thrombolysis or anticoagulation following stent insertion. There is no evidence that anticoagulation is required in patients in whom there is a good blood flow through the stent at the end of the procedure [246]. Thrombosis in the SVC is not a contraindication to stenting as this can be dealt with by local thrombolysis or dispersed with a mechanical device [253]. Few complications have been reported following stent insertion. Migration of stent into the right ventricle from the SVC has not been reported. The argument against stenting is its cost (approximately £1000 in 1998).

## Superior sulcus tumours

Pancoast [254] used the term 'superior pulmonary sulcus tumour' to describe a carcinoma situated at the extreme apex of the lung. The Pancoast syndrome comprises pain in the lower part of the shoulder and inner aspect of the arm (C8, T1 and T2 distribution) that may be severe and unremitting. It may be accompanied by sensory loss in the same distribution and wasting and weakness of the small muscles of the hand and of the medial forearm, wrist and finger flexors. It is caused by involvement of the lower part of the brachial plexus by tumour. A further neurological component is involvement of the sympathetic chain at or above the T1 (stellate ganglion) level to produce Horner's syndrome (ipsilateral partial ptosis, the appearance of enophthalmos, a small pupil and hypohidrosis of the face). The two radiological components of the syndrome are the presence of an apical mass shadow on the chest radiograph and local evidence of bone destruction, usually of the first and second ribs and/or a vertebral body or transverse process (see Fig. 41.15). Any histological type of lung cancer can occur in this situation and clearly incomplete forms of this syndrome are found.

## Management

The diagnosis is obvious where all components of the syndrome are present, although other diseases such as tuberculosis may occasionally produce confluent apical shadowing that is difficult to distinguish from tumour. In this situation bronchoscopy should be carried out, with the submission of washings for cytology and mycobacterial staining and culture, although the immediate results are often inconclusive. If this is the case and the lesion is thought to be an inoperable tumour, as most are by virtue of neurological or vertebral involvement, then percutaneous needle biopsy may provide histological confirmation of the diagnosis.

The best form of treatment for superior sulcus tumours remains the subject of controversy. These lesions were originally regarded as uniformly inoperable. In 1961 encouraging results were reported for radiotherapy followed by surgical removal of the tumour, usually by lobectomy [255]. This approach, with the addition of refinements such as completion of radiotherapy after surgical healing or placement of radioactive implants if the tumour is found to be unresectable at thoracotomy, continues to find favour in some places [256]. However, the evidence that preoperative radiotherapy improves either resectability or 5-year survival rate is weak [257] and requires confirmation with randomized prospective studies. Some take the view that if the lesion appears resectable after staging, surgery should proceed directly; if the tumour is deemed unresectable, radiotherapy should

be given as a single course. A good result is achieved in over 70% of cases when radiotherapy is given palliatively for pain relief [258]. Patients treated with radiotherapy alone or combined with surgery have a reported 5-year survival rate of 20–30% [257,258].

### **Malignant pleural effusion**

The presence of a malignant pleural effusion, whose origin has been determined by either pleural fluid cytology or pleural biopsy [259], indicates both incurability and a short life expectancy, survival rarely extending beyond 1 year with a median survival of approximately 6 months [260]. Once the diagnosis is certain, aspiration is necessary only if the pleural fluid is of sufficient volume to cause breathlessness. If reaccumulation is rapid or if repeated aspiration is required, then a chemical pleurodesis can be performed using one of a variety of available agents (see Chapter 43). When tetracycline is used for this purpose it may be mixed with local anaesthetic in order to reduce the pleural pain associated with the procedure [261].

### **Intracranial metastases**

The diagnosis of intracranial metastases and the frequency with which they occur have been discussed previously. It is notable that in non-small-cell carcinoma, intracranial metastases are found more commonly with adenocarcinomas and large-cell carcinomas than with squamous cell lesions [262].

Cerebral metastases may present with symptoms of raised intracranial pressure such as headache and vomiting. A personality change or impaired intellectual function is an unusual presentation. Focal or generalized seizures may occur. A motor or sensory deficit or impairment of coordination may become manifest.

### **Management**

If intracranial metastases become clinically evident in a patient who is clearly dying of advanced metastatic bronchial carcinoma, adequate narcotic analgesia may be the most appropriate treatment. Sometimes the general condition of the patient requires more active supportive treatment, even though the prognosis may only be a few months. Improvement is often obtained with oral corticosteroids given in a high initial dose, such as dexamethasone 16 mg daily, thereafter gradually reducing according to response. The results of treatment with cranial irradiation are discussed above, symptomatic relief being seen in up to 80% of patients.

Surgical treatment has a small role in the management of intracranial or brain metastases [263] when the disease can be shown to take the form of a solitary deposit that has arisen following an otherwise successful surgical resection

for primary lung cancer of non-small-cell origin. Before such neurosurgery is undertaken, evidence of other metastatic disease should be excluded by a careful search. This approach is justified since intracranial metastatic disease may be the only extrathoracic site of spread in a few patients [264]. Indeed sometimes the neurosurgery is performed as the primary treatment when the primary bronchial carcinoma remains occult within the chest. Prolonged survival has been seen in a group of patients who subsequently proceeded to thoracotomy [264].

However, the prognosis for the great majority of patients with intracranial metastatic lung cancer is very poor, the overall median survival being variously reported as between 3 and 5 months [143,144]. Those whose symptoms respond to radiotherapy survive twice as long as those who do not [265], but only 14% of all patients are alive at 1 year [266].

### **Tracheal tumours**

The trachea may be involved by direct extension of adjacent tumour or, rarely, may be the site of primary malignancy [267], of which the slow growing and locally invasive adenoid cystic carcinoma is probably the most common type [268]. Tracheal malignancy may occur at any age and may be mistaken for other common disorders such as asthma, the increasing stridor of a few weeks' duration in a young or middle-aged adult being misinterpreted as wheeze. Haemoptysis may also occur.

The chest film is frequently normal but clinical suspicion may be heightened by the characteristic appearance of the flow–volume loop (see Chapter 2). The tumour may be demonstrated by conventional or computed tomography of the trachea (Fig. 41.23). Confirmation is by bronchoscopy, although caution should be exercised in the choice of instrument since the fibroptic bronchoscope may occlude an already narrowed opening. Where the stenosis is critical, biopsy using either instrument may result in complete occlusion of a small orifice.

Ideally, treatment of tracheal tumours is by complete surgical excision. This may not be possible because of the involvement of surrounding mediastinal structures. However, if the disease is apparently confined to the trachea, complete excision has been achieved in some centres using tracheobronchoplastic procedures [269]. Other methods of treatment frequently have to be employed, including radiotherapy, which may be administered externally or endotracheally [270], and laser devices [271]. One series described the use of an Nd–Yag laser in 21 patients with tracheal tumours, of which almost half were primary [272]. The majority were treated as emergencies for impending asphyxia and showed symptomatic benefit, allowing time to be gained for fuller diagnostic evaluation and treatment planning, including the use of further laser treatment, surgery or radiotherapy.

**Fig. 41.23** Tracheal tomogram showing carcinoma (arrowed) arising from right lateral wall above bifurcation.

Sometimes patients with tracheobronchial obstruction not amenable to curative surgery and not helped by radiotherapy may benefit from the insertion of a prosthetic stent [273].

### Quality of life

Traditionally, the outcome of treatment for patients with lung cancer has been measured in terms of the extent and duration of tumour response and patient survival, although differences between treatments as measured by these indices have been small. Since the vast majority of patients with lung cancer are treated with palliative intent, it has become increasingly more relevant to individual patient care and to policy-making to compare the cost, in both human and economic terms, of any gain achieved. Clinicians have therefore turned their attention to trying

to measure not only the length of their patient's survival but also the quality of any such extension of life. This aspect of lung cancer management has recently been comprehensively reviewed [274–276]. The concept of quality of life is largely subjective, varying from individual to individual, and many clinicians regard it as a 'soft science' that is impossible to define or measure scientifically. It is generally agreed that quality of life is multidimensional and involves a number of components, including the impact of disease symptoms, the side-effects of treatment, the ability of the patient to function and their psychosocial well-being. Attempts to measure quality of life should therefore reflect all these domains if possible and emphasis should be placed on the subjective experience of the patient whose quality of life is in question. Recently, attention has focused particularly on the development of questionnaires completed by patients themselves.

### Methods for measuring quality of life

Measurements of a patient's level of physical ability (performance status) and the response to treatment and its toxic effects are generally assessed by physicians. The Karnofsky Performance Index [277] has been in use for many years and is still widely favoured as a prognostic indicator. The WHO [278] and Eastern Cooperative Oncology Group [279] scales share many of the same limitations, scoring being influenced by whether the evaluation is performed at home or in hospital, with poor interindividual reliability. These instruments all neglect psychosocial variables and to this extent remain unsatisfactory as measures of quality of life (Table 41.11).

A bewildering array of questionnaires that attempt to measure different aspects of the patient's experience of quality of life [275] has been developed specifically for patients with cancer. These involve visual analogue self-assessment scales, diary cards [180] and, more recently, a modular approach where questions covering general cancer-related features are combined with those specific to lung cancer. The European Organization for Research on the Treatment of Cancer has developed such an instrument over several years [280]. This has a 30-item self-reporting questionnaire for use in cancer clinical trials, with a 13-item module specifically relevant to patients with lung cancer, for example covering cough, dyspnoea, pain and treatment-related side-effects [281]. The instrument is responsive to clinical change and has proved acceptable to patients. Other quality-of-life instruments that have proved popular and valid in the management of patients with lung cancer include the Rotterdam Symptom Checklist [282] and the Hospital Anxiety and Depression Scale [283].

There are surprisingly few reports of quality-of-life measurements in patients undergoing treatment for lung cancer, although things are improving [275]. As most

**Table 41.11** Comparison of Karnofsky [277], European Cooperative Oncology Group (ECOG) [279] and World Health Organization (WHO) [278] scales used to measure performance status.

Karnofsky scale		ECOG/WHO scale	
Status	Score	Score	Status
Normal; no complaints or evidence of disease	100	0	Able to carry out normal activity
Able to carry on normal activity; minor signs or symptoms of disease	90	1	Restricted in physically strenuous activity but ambulatory and capable of light work
Normal activity with effort; some signs or symptoms of disease	80		
Cares for self; unable to carry on normal activity or to do active work	70	2	Ambulatory and capable of all self-care. Unable to work. Up and about >50% of waking hours
Requires occasional assistance but is able to care for most personal needs	60		
Requires considerable assistance and frequent medical care	50	3	Capable of only limited self-care, confined to bed or chair >50% of waking hours
Disabled; requires special care and assistance	40		
Severely disabled; hospitalization is indicated, although death not imminent	30	4	Completely disabled. Cannot carry out self-care. Confined to bed or chair
Very sick; hospitalization and active supportive treatment necessary	20		
Moribund; fatal processes progressing rapidly	10		

patients can only expect some palliation rather than significant prolongation of survival, there would appear to be a strong case for including measurements of quality of life in any future study. Indeed, there is an argument that measurement of quality of life should be part of the routine assessment of patients undergoing any form of intervention and that quality of life should be used to evaluate treatment outcomes in clinical trials. The data obtained could provide an objective basis for informed decision-making for individual patients and for making the case for allocation of appropriate resources to medical and supportive services [284,285].

## Prognosis

It is evident that lung cancer is not a single disease and any discussion of prognosis therefore requires qualification. However, if all types of lung cancer are considered together, the overall survival 5 years after diagnosis is 5–15% [122,286]. More meaningful results include details such as tumour histology, surgical stage, the type of treatment used, the performance status of the patient and the length of follow-up.

Some authors take the view that the growth of micro-

scopic lung cancer is approximately exponential, duration of survival being a function both of the size of the tumour at diagnosis and its doubling time [287,288]. Doubling time can be crudely calculated using a mathematical equation [289]: for small-cell carcinoma it is approximately 50 days, for squamous and large-cell carcinoma approximately 100 days and for adenocarcinoma about 180 days [290,291]. The shorter doubling time for small-cell carcinoma is in keeping with its poor overall prognosis, although the longer doubling time of adenocarcinoma appears to give it no prognostic advantage over squamous and large-cell carcinoma. A tumour cell with a diameter of 10  $\mu\text{m}$  produces a 1-cm diameter nodule weighing approximately 1 g after 30 doublings. It is therefore clear that in the lifespan of a tumour the majority of doublings must take place before the tumour is either clinically or radiographically detectable [292]. If exponential growth rates are assumed and if the tumour has arisen from a single cell, it is possible to extrapolate backwards to show that slow-growing tumours such as adenocarcinoma and squamous carcinoma may have been present for about 8–15 years prior to diagnosis and small-cell lesions for up to 3 years [288]. The natural history of lung cancer therefore is one of years of unrecognized growth from a single

cell, with the tumour becoming clinically apparent just prior to death. The clinician thus has very little chance of having any impact on what is the end stage of a condition. It is extremely disappointing that methods are not available to detect the disease in the preclinical state and large screening studies that have attempted to do this have had no impact on survival [293–296].

### Non-small-cell carcinoma

The overall prognosis for patients presenting with non-small-cell lung cancer is poor and survival rates have not changed over the last several decades. In large series of unselected patients, 5-year survival rates for this group of patients lie between 4 and 7%, irrespective of whether the patient received surgery, radiotherapy or chemotherapy [115,297].

The results of treatment in non-small-cell lung cancer have been well documented. Stage I tumours (T1/T2N0M0) when treated surgically carry a 5-year survival rate of 30–60% [122,298]. Unfortunately only about 20% of lung cancers are found to be stage I and the prognosis worsens as the stage advances. Thus for stage II tumours treated surgically, the survival rate falls to 20–40% at 5 years [122]. Studies that have examined radiotherapy as an alternative treatment to surgery in stage I and stage II non-small-cell lung cancer suffer from the disadvantage of lacking accurate pathological typing and staging, which is more easily achieved in surgically treated patients. Results reported show survival rates ranging from 6% at 4 years [126] to 40% at 5 years [146].

More extensive disease, where surgery is more difficult, carries an exceptionally poor overall outlook irrespective of treatment. Survival at 12, 24 and 60 months for stage IIIA disease is 37.7%, 12.7% and 6.1%, respectively, whereas for stage IIIB it is only 31.8%, 10.8% and 3.9% [299]. Patients with the least dismal outlook in this group are those with good pretreatment performance status and those with squamous histology. In the presence of distant metastases (stage IV disease), 1-year and 2-year survival is 19.8% and 5.4% respectively.

### Other prognostic factors

An analysis of prognostic factors in lung cancer found that for some surgically inoperable non-small-cell tumours the dominant factors were initial performance status and extent of the disease as determined by staging [300]. Other factors, such as anorexia, significant weight loss (>10% of body weight) and breathlessness, were relevant to a lesser degree. For operable non-small-cell lung cancer the most important prognostic factors were the stage of disease and, to a much lesser degree, the histological type and degree of differentiation [301]. The prognosis in so-called scar carcinomas is dependent upon the stage and histological type of the tumour, the associated scar being of aetiological rather than prognostic significance [44].

### Small-cell carcinoma

Untreated patients with small-cell lung cancer have a median survival of 2.8 months [302,303]. Those who have limited disease (i.e. confined to one hemithorax including ipsilateral supraclavicular nodes) have a median survival of 3.1 months compared with 1.4 months for the remaining majority (70%) who have more extensive disease. Aggressive chemotherapy extends the median survival for limited and extensive disease to about 14 and 8 months respectively; 15–20% of those with limited disease treated in this fashion survive for more than 2 years compared with less than 2% for those with extensive disease [167–169]. A very small proportion (<5%) may have stage I disease and 5-year survival rates of around 30% have been reported for these patients when treated surgically [205].

It is disappointing that there has been little change in the prognosis of all patients with lung cancer over the last three decades. This is almost certainly due to the fact that most patients present with advanced disease and effective systemic therapy is not available. While effective anti-smoking campaigns would have a profound effect on the incidence of the condition in the long term, what is urgently required is newer agents with activity in patients with established metastatic disease.

# OTHER PULMONARY NEOPLASMS AND RELATED CONDITIONS

ANTHONY SEATON

The previous chapter describes the various types of bronchial and alveolar cell carcinomas. Apart from metastases, all other lung tumours are relatively rare, in one series from the Mayo Clinic comprising less than 1% of all primary lung tumours [1]. In that series, the most common were non-Hodgkin's lymphoma, carcinosarcoma and mucoepidermoid carcinoma, representing 41, 20 and 15%, respectively. This chapter deals with these other primary lung tumours, both benign and malignant, and also gives a brief account of the different patterns of lung metastases from tumours of other organs. It includes a description of some diseases that, though not strictly neoplastic, are related to the tumours described. An attempt is made to classify the primary tumours according to the tissue from which their cell type originates, although in a number of cases this is uncertain. The classification adopted is given in Table 42.1. For further pathological information on the many different types of lung tumour, the reader is referred to the bibliography of Whimster [2].

## Tumours of the blood and reticuloendothelial system

### Hodgkin's lymphoma

The clinical syndrome described by Thomas Hodgkin in 1832 is now taken to be confined to a particular histological type of lymphoma characterized by destruction of lymph node architecture, proliferation of large abnormal cells derived from monocytes and, usually, Reed-Sternberg cells (Fig. 42.1). It may be subclassified into four histological types: nodular sclerosing, lymphocyte-predominant, mixed cellular and lymphocyte-depleted. Nodular sclerosing Hodgkin's lymphoma tends to be the most benign variant, the other types often progressing from lymphocyte-predominant through mixed to lymphocyte-depleted. It is usual to classify Hodgkin's disease according to its extent, the tissues involved and the presence of systemic symptoms [3], this classification

being used in prognosis and in the planning of treatment (Table 42.2).

### Clinical features

Hodgkin's disease primarily affects adults, with an annual incidence of 2–3 per 100 000, and peaks at the ages of 25 and 60–70. It is more common in men. Only occasionally does it present as a primary intrathoracic lesion, when it is usually found as a result of investigation of enlarged hilar nodes. They are usually asymmetrically enlarged, in contrast to those of sarcoidosis, and the disease commonly extends into the mediastinal and paratracheal nodes (Fig. 42.2). More frequently, these features are part of a more generalized lymphadenopathy. The patient may be free of symptoms or may have evidence of systemic disease, with fever, loss of weight or night sweats. Symptoms referable to intrathoracic disease may include pleuritic pain, cough due to bronchial or tracheal compression, stridor, hoarseness due to recurrent laryngeal involvement, facial swelling due to vena caval obstruction, or breathlessness due to pulmonary infiltration [4]. Very rarely, the first presentation of the disease may be a diffuse intrapulmonary infiltrate without node enlargement [5,6]. Again, it is more usual for pulmonary infiltration to be found as part of a generalized disease, and usually associated with involvement of the hilar and mediastinal lymph nodes. In one review of 284 patients with Hodgkin's disease, 52% were found to have intrathoracic involvement; in 43% this was in the lung, in 34% hilar nodes, in 23% mediastinal nodes and in 11% pleura [7]. Thus node involvement is not essential for the diagnosis of pulmonary Hodgkin's, the disease manifesting itself wherever there is lymphatic tissue in the lung [8].

Apart from mediastinal and hilar node involvement, the radiological features of intrathoracic Hodgkin's disease most frequently show peribronchial infiltration. Direct extension from involved nodes is the next most frequent appearance, while patchy infiltrates, diffuse pneumonic consolidation and nodular lesions occur rather less often

[7] (Fig. 42.3). Pleural effusion and direct spread into ribs may occur. All histological types of Hodgkin's disease may involve the lung, although the lymphocyte-predominant type does so less frequently than do the others. Involvement of the lung, as opposed to intrathoracic nodes, tends to be a later feature of Hodgkin's disease, though it is found at presentation in about one-third of patients [7]. It generally appears between 1 and 4 years after presentation, albeit the early use of chemotherapy may well prevent its development in many cases.

The diagnosis of intrathoracic Hodgkin's disease is made by biopsy of appropriate tissue. The main differen-

**Table 42.2** Staging of lymphoma.

Stage I	Involvement of a single lymph node region (I) or of a single extralymphatic organ or site (I <sub>E</sub> )
Stage II	Involvement of two or more lymph node regions on same side of the diaphragm (II) or localized involvement of extralymphatic organ or site and of one or more lymph node regions on the same side of the diaphragm (II <sub>E</sub> )
Stage III	Involvement of nodes on both sides of the diaphragm (III). There may also be splenic involvement (III <sub>S</sub> ), localized involvement of extralymphatic organ or site (III <sub>E</sub> ) or both (III <sub>ES</sub> )
Stage IV	Diffuse or disseminated involvement of one or more extralymphatic organs or tissues with or without associated lymph node enlargement
Each stage is divided into A, those with no systemic symptoms, and B, patients with night sweats, loss of more than 10% of body weight in 6 months or unexplained fever above 38°C	

tial diagnosis is sarcoidosis (see Chapter 39), which also commonly presents with hilar, mediastinal and other node enlargement but less frequently causes systemic symptoms, fever and weight loss. At first presentation, it is usual to be able to obtain a node from a more accessible part of the body; however, if the disease is confined to the thorax, mediastinoscopy, mediastinotomy or thoracotomy is necessary, since needle biopsies are insufficient for proper histological assessment. Assuming the diagnosis can be made from an involved node, it may not be necessary to biopsy lung as well. However, if thoracotomy is performed, it is sensible to take a lung biopsy as well as a node. If the disease presents as a primary intrapulmonary lesion, biopsy is necessary, as it is if the lung shadowing occurs after the start of treatment. In this case, differentiation has to be made from other causes of lung infiltration that may affect people immunosuppressed by drugs, radiotherapy or the primary disease, including infections by *Pneumocystis carinii*, fungi and mycobacteria. Trans-bronchial biopsy with brushing and lavage have proved to be the investigations of choice in this situation. Other rare pulmonary complications of Hodgkin's disease include Langerhans' cell histiocytosis (histiocytosis X) and veno-occlusive disease [9,10].

### Treatment and prognosis

Treatment is planned on the basis of a staging procedure that usually includes CT, unless the disease is clearly stage IIIB or IV. Laparotomy and splenectomy were widely used in the past but probably confer no survival advantages and carry definite risks, so are rarely used nowadays.

**Fig. 42.1** Histological appearances of pulmonary deposit of nodular sclerosing Hodgkin's disease showing fibrosis to the left and a nodular tumour deposit to the right. This contains a background of small cells/lymphocytes, eosinophils and plasma cells mixed with large pleomorphic cells. One Reed-Sternberg cell is present in the centre of the nodule (haematoxylin & eosin  $\times 150$ ).

**Fig. 42.2** Enlarged right hilar and paratracheal nodes in 18-year-old girl that proved to be due to nodular sclerosing Hodgkin's disease.

Intrathoracic disease is rarely stage I. Stage IA and IIA disease are usually managed by megavoltage radiotherapy, although clear-cut symptoms of B disease lead to treatment with chemotherapy. Stages III and IV are treated with chemotherapy, usually without radiotherapy. Treatment differs in different centres, although chemotherapy is normally started with a combination of nitrogen mustard, vincristine or vinblastine, procarbazine and prednisolone, given for at least six courses. The different regimens and their immediate and long-term side-effects are best managed by a specialist oncologist [11]. Patients receiving both radiotherapy and chemotherapy are

known to have a much increased risk of developing other neoplasms [12]. In a recent series from The Netherlands, a second tumour occurred in 146 of 1939 patients over a mean follow-up of 9 years, over three times the expected rate [13]. The tumours with highest relative risks were leukaemia, non-Hodgkin's lymphoma, sarcoma and melanoma.

The prognosis in treated intrathoracic Hodgkin's disease is no worse than when any other part of the body is involved; at 10 years, some 75% of patients with stage II disease, 58% with stage III and 40% with stage IV may expect to be alive, most without relapse.

**Fig. 42.3** Posteroanterior (a) and left lateral (b) chest films of 20-year-old girl with anterior mediastinal Hodgkin's disease. There was spread of lymphoma into the lingula anterior to the left hilum.

### **Non-Hodgkin's lymphoma**

The term 'non-Hodgkin's lymphoma' includes several other malignant lymphoproliferative conditions that do not show the pathological features of Hodgkin's disease,

including those previously known as lymphosarcoma and reticulum cell sarcoma. Their classification (there are several in use) is confusing to the non-specialist but one, the Kiel classification [14], is given in Table 42.3. This is based on cell-marker and cytological studies and has some

value prognostically, in that the high-grade tumours are the more malignant.

**Clinical features**

Non-Hodgkin's lymphoma is characteristically a disease of older people, with a peak incidence in those aged 60–80. Little is known of its pathogenesis, though it may affect people who have immune disturbances as a result of either disease, such as Sjögren's syndrome and coeliac disease, or immunosuppressive drugs. Epstein–Barr virus may be responsible in some cases, probably acting with another factor such as persistent stimulation of the immune system by another infection. In other cases infection with human T-cell leukaemia virus (HTLV)-1 may be responsible. Thoracic involvement most commonly takes the form of enlarged hilar and mediastinal nodes, although intrapulmonary involvement may occur, appearing as diffuse consolidation, peribronchial infiltration or single or multiple nodular lesions [15]. Pleural effusion is not infrequent. Altogether, intrathoracic involvement occurs in 20–25% of cases [16,17], with node enlargement and pleural effusion in about 20% and lung involvement in about 25%. Enlarged nodes may occur in any of the pathological types; however, lung infiltration is most frequent with the low-grade lymphocytic type

whereas nodular lesions occur, probably as blood-borne metastases, in the high-grade lymphoblastic types [17].

Primary lung involvement by non-Hodgkin's lymphoma is very rare. It presents with non-specific symptoms, including cough, breathlessness, chest pain and loss of weight [18,19]; finger clubbing and hypertrophic osteoarthropathy have been described [20]. Occasionally a lesion is found on routine radiography of a fit patient. The chest film usually shows a single area of diffuse infiltration, which may be nodular or involve as much as a whole lung [18]. Pathologically these are often low-grade lymphoplasmacytoid lesions (immunocytomas) [21].

The diagnosis of non-Hodgkin's lymphoma is made in the same way as that of Hodgkin's disease, i.e. an adequate piece of tissue is required for proper assessment. If the lung is involved at first presentation together with other organs, no further pulmonary investigation may be necessary, at least until there has been no response to antibiotics (in case of a pneumonic complication) and chemotherapy. However, sputum cytology is a useful non-invasive investigation [22]. If the only manifestation of disease is an intrathoracic lesion, mediastinoscopy and thoracotomy may well be necessary. Indeed, long-term remission has followed surgical removal of lymphocytic lymphoma confined to the lung [23].

In the case of lung infiltration occurring after diagnosis and initiation of treatment, other diagnostic measures are necessary, as the lesion may be due to opportunist infection. Transbronchial biopsy, together with brushing and local lavage, are the best techniques short of the more invasive procedures of thoracotomy or video-controlled thoracoscopy [24].

**Treatment and prognosis**

This is a matter for the specialist oncologist. In general, non-Hodgkin's lymphomas have a poorer outlook than the Hodgkin's type, and patients with the less-differentiated high-grade tumours, especially when they present with systemic symptoms, tend not to survive more than 2 years. However, in the few such patients who do respond to treatment, cure is possible; paradoxically at present, it is probable that low-grade tumours almost never respond completely to treatment [25]. The aim of management should therefore be to treat low-grade tumours with the minimum therapy necessary to relieve symptoms and ensure a good quality of life, whereas high-grade tumours should be treated with combination chemotherapy. Stage I disease and low-grade tumours, including chronic lymphatic leukaemia, have a much better prognosis, with 70% survival at 3 years [26]. Pulmonary infiltration occurring after the start of chemotherapy not surprisingly carries a worse prognosis than if it is found to be present *ab initio*. Treatment of stage I disease is usually with local radiotherapy. Low-grade lymphomas

are often treated with cyclophosphamide or chlorambucil alone, and some are not treated at all; the age of the patient, the course and cell type of the disease and the potential toxicity of the drugs are all factors that should be taken into account when planning treatment. Pulmonary involvement almost always requires treatment and this is usually radiotherapy combined with chemotherapy. The higher-grade lymphomas would normally be treated with combinations such as cyclophosphamide, vincristine and prednisolone, with or without doxorubicin and bleomycin. It should be remembered that these drugs themselves can be the cause of diffuse pulmonary infiltrates (see Chapter 55).

### Leukaemias

Chronic lymphatic leukaemia is now regarded generally as a variant of low-grade lymphocytic lymphoma in which the abnormal cells are found in the bloodstream. Involvement of intrathoracic nodes and of lung may occur, as discussed above [17]. Hilar adenopathy may occur in acute leukaemias as part of a generalized lymphadenopathy. Acute and chronic myeloid leukaemia may involve the lung secondarily, but usually only with microscopic

infiltration [27,28]. Thus the finding of pulmonary infiltrates in a patient with leukaemia should arouse the suspicion of either opportunist infection or lung haemorrhage. In acute leukaemias there is a strong case for instituting empirical treatment without further investigation, since such patients with pulmonary infiltrates usually die very rapidly (discussed further in Chapter 52). Briefly, treatment entails the administration of platelets if the platelet count is low and broad-spectrum antibiotics, including high-dose co-trimoxazole and amphotericin. If investigation is to be carried out, bronchoalveolar lavage or transtracheal aspiration is probably the safest and least traumatic [29,30].

### Plasmacytoma

The respiratory system is rarely involved in multiple myeloma, although deposits may occasionally be found presenting as tumours of trachea or bronchi [31,32]. Even less frequently, a solitary lung plasmacytoma may be the only manifestation of the disease [33]. A more usual presentation to the chest physician is an osteolytic lesion of rib or sternum associated with an intrathoracic extension of tumour (Fig. 42.4).

**Fig. 42.4** Expansion and irregular destruction of sternum due to myeloma.

**Fig. 42.5** (a) Electron micrograph of Langerhans' cell from patient with Langerhans' cell histiocytosis showing multiple characteristic tennis racquet or Birbeck bodies (uranyl acetate and lead citrate  $\times 33\,700$ ). (b) High-power view of three Birbeck bodies showing their tubular structure and terminal dilatation ( $\times 63\,500$ ).

The finding of a monoclonal band of immunoglobulin on electrophoresis of serum proteins is characteristic of myeloma, and such a band would be expected with solitary plasmacytoma of lung. However, it should be remembered that monoclonal gammopathies may be associated with other lesions, especially lymphoma, and may occur without obvious cause in association with a range of pulmonary diseases [34].

A solitary plasmacytoma is likely to be diagnosed at bronchial biopsy. The treatment of choice is probably excision, which has been associated with prolonged remission. Disseminated disease may occur subsequently but is not inevitable. Treatment of generalized myeloma with lung involvement would probably include local radiotherapy and chemotherapy with melphalan and prednisone. Multiple-drug therapy is not yet established as having substantial advantages, although in some patients with aggressive disease vincristine, doxorubicin and dexamethasone or similar combinations have been used to produce a remission.

### Histiocytoses

A number of conditions are characterized by abnormal proliferation of histiocytes; although not all are neoplastic, they are considered together here. All are extremely uncommon. Their classification has been changed frequently and at present they are differentiated into Langerhans' cell histiocytosis, histiocytoses of non-Langerhans' phagocytic cells, malignant histiocytoses, and a mixed bag of other histiocytoses. Langerhans' cell histiocytosis is the agreed name for the syndrome previously known by several names: histiocytosis X, eosinophilic granuloma, Hand-Schüller-Christian syndrome and Letterer-Siwe

disease [35]. Lung involvement is not uncommon and is described below. Malignant histiocytosis as described in the literature, a disease predominantly of young people and which may arise in the gastrointestinal tract of patients with coeliac disease, would probably now be regarded as histiocytic lymphoma. Lung involvement with diffuse acinar infiltrates is not uncommon at some stage in the course of the disease and occasionally pulmonary symptoms may be the presenting feature [36–38]. Lung disease is not a feature of the other histiocytoses.

### Langerhans' cell histiocytosis

Langerhans' cell histiocytosis was originally thought to be a lipid storage disease but is now classified as a condition of histiocytic proliferation [39]. Langerhans' cells are derived from the bone marrow and normally found in the skin. They secrete interleukin (IL)-1 and prostaglandin E and promote secretion of IL-2 and interferon  $\gamma$  by T lymphocytes. Pathologically, the disease is characterized by proliferation of histiocytes with vesicular and lobulated nuclei, basophilic nucleoli and eosinophilic cytoplasm. Tissue necrosis and infiltration with lymphocytes, plasma cells and eosinophils are also seen. The histiocytes may be seen on electron microscopy to contain characteristic Birbeck or tennis racquet bodies [40,41] (Fig. 42.5). Deposits of lipid material may be seen in the cytoplasm of the histiocytes. A spectrum of appearances may be present in lesions, from histiocytic infiltrates through granulomas and lipid-containing lesions to fibrosis.

Clinically, the disease affects infants and children primarily but may present as late as the fifth decade [42]. Its peak incidence is in the first few years of childhood and becomes progressively less frequent thereafter. The three original names reflect three characteristic clinical groups: group 1, in which there is primarily bone involvement (eosinophilic granuloma); group 2, in which bone and other organs such as lung, lymph nodes and liver are involved (Hand-Schüller-Christian disease); and group 3, in which skin, viscera and bone are involved (Letterer-Siwe

Siwe disease). However, there is considerable overlap between the three. In general group 1 lesions have the best prognosis and group 3 the worst. Age is also an important prognostic factor, very young children having a bad prognosis [43]. The condition is uncommon, having been estimated to occur in 1 per 350 000 annually in the UK [44].

The symptoms vary depending on the site of disease. Skin lesions present as papular and vesicular eruptions. Bone lesions often involve the skull, ribs and femur and may be palpable as subcutaneous lumps. Radiology shows punched-out lytic areas (Fig. 42.6). Granulomatous polyps may present in the external auditory meatus or in the orbit causing exophthalmos. Diabetes insipidus is a rare feature due to infiltration of the hypothalamus. When the lung is involved in the generalized disease, the prognosis has usually been thought to be bad [43]; however, a more recent study in which special efforts were made to detect subtle evidence of lung involvement suggests that this is not necessarily the case [45]. Involvement of the lung alone, primary pulmonary Langerhans' cell histiocytosis, may occur at any age but is seen most commonly in young male adults and seems to be associated with smoking [46]. All forms of the disease have a natural tendency to burn out, leaving fibrosis in the case of lung involvement, and the primary lung form is not necessarily associated with a fatal prognosis [47]. The onset is insidious, with cough, shortness of breath and loss of weight. Pneumothorax may be a presenting feature and is a frequent complication of all stages of the disease [48], often occurring repeatedly.

The radiographic appearances are of a diffuse pul-

Fig. 42.6 Skull radiograph of patient with Langerhans' cell histiocytosis showing punched-out lesion in occiput.

monary infiltration with a mixture of small nodular and irregular reticular shadows [49] (Fig. 42.7). There is no characteristic distribution, except that several zones of both lungs are involved and the costophrenic angles are often spared. Cyst formation is common and becomes a more marked feature as the disease progresses; some patients develop diffuse emphysematous changes. There is a tendency for nodular opacities to progress to cysts, reflecting histological changes from granuloma to fibrosis. High-resolution CT may show a characteristic combination of nodules and cystic change in keeping with these pathological features (see Fig. 7.49) [46]. Pleural effusion and mediastinal node involvement are rare [50,51].

The diagnosis is usually made by lung biopsy, although electron microscopy of lavaged bronchoalveolar cells may show the characteristic X bodies [41] (see Fig. 42.5). Monoclonal antibodies have been shown to be of value in the histological diagnosis [52–54]. Clinically, the diagnosis is suspected in a young male with diffuse reticulonodular radiographic change, especially if associated with pneumothorax; sarcoidosis is the disease most likely to cause confusion. Pulmonary function tests usually show reduced diffusing capacity but normal or increased lung volumes [40].

There is no consensus on treatment of Langerhans' cell histiocytosis. Spontaneous remissions may occur or the disease may pursue a rapidly downhill course over 2 years. The primary pulmonary type, as opposed to pulmonary involvement in the generalized disease, may often appear to arrest or, more usually, to progress rather slowly to diffuse honeycombing or emphysema and pulmonary hypertension. Survivals up to 20 years from diagnosis have been reported. In the present state of knowledge, it is probably wise to review the patient several times over a few months, with careful radiographic and functional assessment of any progression, before starting treatment [55]. The first line should probably be a course of high-dose prednisolone [56]. If this is ineffective over 3–4 months, consideration should be given to chemotherapy with chlorambucil, methotrexate, vincristine or, possibly, interferon  $\alpha$  [44,57]. If the disease has already reached the fibrotic stage, treatment is unlikely to be of value; in suitable patients transplantation may be considered, though recurrence after this procedure has been reported [58,59]. Pneumothoraces are often recurrent and pleurodesis may be necessary.

### Histiocytoma

Although the nomenclature of histiocytomas is confusing, there is a very rare benign tumour, which may be a neoplasm or possibly a granulomatous reaction, composed predominantly of histiocytes that occurs in the lung or bronchus [60,61]. The lesion may contain mast cells and spindle cells, and has also been called xanthoma or mast

**Fig. 42.7** Diffuse fine nodular and irregular infiltrates in a patient with Langerhans' cell histiocytosis.

cell granuloma. In addition, a fibrous histiocytoma has been described that usually presents as a small round lung lesion and which may occasionally metastasize [62,63]. It also is very rare and is probably analogous to the more common fibrous histiocytoma of the skin. One study of the pathology of these pulmonary tumours has distinguished benign, borderline and unequivocally malignant fibrohistiocytomas [64], and has reviewed the clinical correlates. Recurrence occurred occasionally after resection in the benign and intermediate groups as well as in the malignant. Pathological features of the malignant tumour linked to a poor prognosis included necrosis, bizarre giant cells, frequent mitoses and high cellularity. Those subjects with malignant tumours had a significant mortality. The niceties of diagnosis of these lesions and their cell of origin, if they are all indeed neoplastic, depend on electron microscopy and special histochemical techniques.

### **Lymphoproliferative conditions**

Several conditions characterized by proliferation of lymphocytes within the lung have been described. These include lymphoid interstitial pneumonia and pseudolymphoma, lymphomatoid granulomatosis (see Chapter 40) and plasma cell granuloma. The first two appear to be monoclonal proliferations of B lymphocytes and are therefore properly classified as low-grade lymphomas [65,66]. They may be associated with paraproteinaemia [67]. Evolution to clinically progressive lymphoma occurs but usually over a long time-scale, such that malignant change

often does not become apparent in the adult. The conditions are recognized complications of Sjögren's syndrome [68], human immunodeficiency virus (HIV) infection [69,70], bone marrow transplantation [71], primary biliary cirrhosis [72] and agammaglobulinaemia [73], and occasionally occur in families [74].

### **Lymphoid interstitial pneumonia**

This condition may cause no symptoms or may present with cough and shortness of breath. Chest films show a diffuse interstitial infiltrate, often bilateral but occasionally localized to a lobe or segment, when it may be mistaken for an infective pneumonia. The patient is often found to have paraproteinaemia. It may be associated with enlargement of the liver and peripheral lymph nodes. Histologically, the lung shows a diffuse infiltration of alveolar walls with mature lymphocytes and some plasma cells and histiocytes [75] (Fig. 42.8). The condition rarely if ever progresses to diffuse fibrosis, though evolution to malignant lymphoma [67] and lymphomatoid granulomatosis [76] has been described. It may respond to treatment with high-dose corticosteroids; if these are not successful, cyclophosphamide, chlorambucil or azathioprine may be effective [23,75]. Occasionally, as in one patient with acquired immune deficiency [69], spontaneous remission may occur; if the patient is symptom-free and without serious pulmonary impairment, a case may be made for withholding treatment and observing progress, as with other low-grade B-cell lymphomas.

**Fig. 42.8** Lung biopsy of patient with lymphoid interstitial pneumonia showing accumulation of lymphocytes in alveolar walls with follicle formation (haematoxylin & eosin  $\times 45$ ).

### **Pseudolymphoma**

These tumours are probably best regarded as the early stage of lymphocytic interstitial pneumonitis, where the disease process is still confined to the bronchial mucosal lymphoid tissue. They are thus sometimes referred to as MALT or BALT tumours. They are differentiated from malignant lymphoma by the presence of infiltration of lung by mature lymphocytes, true germinal centres and the absence of local node involvement [23,77]. They may present, usually in the middle-aged, with fever, breathlessness and general malaise [78], although they may be an incidental finding on a chest radiograph as a solitary lesion, a pneumonic infiltrate or as several discrete lesions. While they appear generally benign, change to (or subsequent development of) malignant lymphoma has been described [79,80]. Surgical removal has been followed by relief of symptoms [23] and this is the most likely method of management since most are removed under suspicion of being carcinomas. Otherwise they should be managed conservatively as other B-cell lymphomas.

### **Plasma cell granuloma**

This lesion, not to be confused with the rare primary plasmacytoma or with metastatic myelomatous deposits, is probably not a true neoplasm. It usually presents as a symptomless coin lesion on chest radiography but may cause bronchial obstruction and distal collapse or even diffuse lobar infiltration. It occurs predominantly in children and young adults and usually arises from a bronchus. Histologically it is composed of plasma cells, lymphocytes and histiocytes in a fibrous stroma [23,81]. Variations in this pattern may cause it to be confused with

other conditions, such as plasmacytoma or histiocytoma; however, plasma cell granuloma is always benign.

### **Tumours of epithelium**

These tumours, sometimes in the past loosely and misleadingly termed pulmonary adenoma, comprise 1–2% of pulmonary neoplasms. The most common is carcinoid tumour, followed by cylindroma. The others are very uncommon indeed.

#### **Carcinoid tumour**

This is not only the most common of the tumours originally grouped as bronchial adenoma but also the least rare of the primary lung tumours presenting in childhood [82–85]. It arises usually from a main or segmental bronchus and can often be seen bronchoscopically as an intraluminal tumour, generally covered with intact epithelium. This may be associated with spread into adjacent lung, so that the tumour may be larger than at first appears. Occasionally the tumour arises in peripheral lung. It is a neoplasm of the bronchial endocrine or APUD cell (see Chapter 1) derived from the primitive gut and therefore has the potential, rarely realized in bronchial carcinoid, to secrete substances responsible for various paraneoplastic syndromes. Histologically, it is composed of sheets or aggregates of small cells with dark central nuclei and pale cytoplasm in a vascular stroma. Often a pseudoglandular pattern is seen [86] (Fig. 42.9). So-called atypical carcinoid tumours show increased mitotic activity, irregular nuclei and prominent nucleoli, and areas of tissue necrosis [87]. These may have a greater potential to metastasize and are more difficult to distinguish from oat-cell

**Fig. 42.9** Histology of pulmonary carcinoid tumour showing regular polygonal cells with small round nuclei, forming regular trabeculae (haematoxylin & eosin  $\times 300$ ).

carcinoma. Occasionally, amyloid material [88] or bone [82] may be laid down in the stroma of carcinoid tumours. When histological diagnosis is difficult, special stains may demonstrate the various neuropeptides [85] and electron microscopy may be helpful, showing the neurosecretory material as dense rounded granules (Fig. 42.10).

### Clinical features

Carcinoid tumours, being predominantly slow-growing intrabronchial lesions, usually present with haemoptysis or symptoms due to bronchial obstruction [89,90]. They occur equally in either sex, usually at a younger age than bronchogenic carcinoma; the median age is between 40 and 50. About half of patients present with episodes of recurrent infection in the same lobe, one-third with haemoptysis, and small proportions with chest pain, cough, wheeze or shortness of breath [82]. The tumour may also be found on routine chest radiography in a symptom-free individual, especially if it is a peripheral one.

Important clinical features may be recurrent pneumonia, sometimes over several years [91], unilateral monophonic wheeze and signs of obstructive emphysema (see Chapter 6) [92]. These signs, which may be as subtle as slight reduction in movements and breath sounds over the affected lobe associated with a normal percussion note, are particularly important for detecting central tumours where the radiograph may not show an obvious abnormality.

Most patients have an abnormal radiograph at presentation [82], usually showing segmental or lobar collapse or consolidation. Discrete tumour may be seen in about one-quarter of cases and, especially in patients presenting with wheeze, the only abnormality may occasionally be lobar hyperinflation related to obstructive emphysema [92]; if

**Fig. 42.10** Electron micrograph of carcinoid cell showing dense rounded granules of neurosecretory material (lead citrate and uranyl acetate  $\times 4860$ ).

this is suspected, it may be confirmed by taking a film on expiration. All three features may be mimicked by bronchial carcinoma or other endobronchial lesions and inhaled foreign bodies, so diagnosis requires biopsy. This would normally be carried out at fiberoptic bronchoscopy, although caution should be used in interpretation of any such biopsies as there is much scope for confusion with oat-cell carcinoma when only small pieces of tissue are available to the pathologist. If the suspicion of carcinoid is raised, it is probably wise to obtain a larger biopsy via the rigid bronchoscope, since surgical treatment may well differ depending on which of these two neoplasms is present.

Very rarely, carcinoid may present with diffuse multi-

centric endobronchial lesions [88] or as multiple peripheral tumours [93], often associated with bronchiectasis and scarring. These latter lesions have been called tumourlets [94].

All forms of carcinoid have the potential to metastasize, though this probably occurs in fewer than 10% of treated cases. Metastasis may occur to local nodes, to liver and to bone particularly; in bone the lesions tend to be osteoblastic. Metastases may present clinically many years after surgical removal of the primary tumour, although when they do so the patient may still survive several years, with or without treatment.

The carcinoid syndrome, characterized by attacks of intense flushing, tachycardia, occasionally wheeze, and hypotension, occurs in approximately 1% of patients with bronchial carcinoid [95,96]. Other features may be abdominal cramps and profuse watery diarrhoea, oedema of the face and arms, symptoms of pellagra and stenotic or regurgitant lesions of the pulmonary and tricuspid valves [97]. Pulmonary carcinoid has been reported to cause mitral valve disease on one occasion [98]. This syndrome seems to be related in part to the carcinoid cell's role in tryptophan metabolism, the amino acid being converted to 5-hydroxytryptophan and then decarboxylated to 5-hydroxytryptamine (serotonin). Release of this substance into the blood may be a cause of the wheeze and diarrhoea, while competition by the tumour for tryptophan may be responsible for the symptoms of pellagra. Subsequent conversion of serotonin to 5-hydroxyindoleacetic acid occurs in the liver; this substance is then excreted in urine where it provides the basis of a useful test for diagnosis of the syndrome. The flush does not seem to be related to serotonin but may be provoked by alcohol, excitement or intravenous norepinephrine (noradrenaline), and may be due to secretion of kinins or vasoactive peptides by the tumour [99]. These substances may also be responsible for fibrous damage to the heart valves, though how this occurs is not clear.

Carcinoid tumour of the lung has also been reported to be associated with Cushing's syndrome [96], acromegaly [100], pluriglandular adenomatosis [101] and hypercalcaemia [102]. These rare occurrences are presumably related to the potential of the APUD cell to secrete hormones or hormone precursors.

### Treatment and prognosis

Carcinoid tumours should be removed surgically [82,83]. At operation it is unusual to find metastases in nodes, although the nodes may be enlarged due to associated infection and frozen section may be advisable. If the tumour is confined to a bronchus, it may be possible to remove it by sleeve resection; otherwise lobectomy or pneumonectomy may be necessary. In general, surgery should be as conservative as possible. After successful

resection, the prognosis is very good, with a better than 90% 10-year survival rate. If endocrine symptoms are present, these are relieved by successful tumour resection. However, metastasis may present even as late as 16 years after resection.

Liver metastases may be treated, and the attendant symptoms palliated, by selective hepatic arterial embolization [82,103]. If symptoms of the carcinoid syndrome are associated with an irresectable or metastasized tumour, which is very rarely the case with lung tumours, control of diarrhoea, flushing and wheeze may be obtained with serotonin antagonists (methysergide or cyproheptadine) and  $\alpha$ -adrenergic blocking drugs. Valvular heart lesions may require surgical treatment, while pellagra may be treated with supplemental nicotinamide. Since the prognosis of carcinoid tumour is relatively prolonged, even when associated with such symptoms and metastases, control of symptoms with this treatment may be an important part of the patient's management.

### Cylindroma (adenoid cystic carcinoma)

This tumour represents only about 15% of so-called bronchial adenomas [104], although it is probably the most common primary malignant tumour of the trachea [105]. Histologically, it originates from bronchial glands and is composed of small round cells with dark nuclei arranged in a cribriform manner, with larger paler cells forming clumps and pseudoacini [96] (Fig. 42.11). The bronchial mucosa usually remains intact.

### Clinical features

Cylindromas may occur at any age and cause haemoptysis and symptoms of bronchial obstruction [96,106]. They should be suspected particularly if a young or middle-aged adult presents with increasing stridor of a few weeks' or months' duration. Radiology of the chest may show a hilar tumour or distal collapse or consolidation; if the tumour arises in the trachea, the film is usually normal. Diagnosis is made by bronchial biopsy, and bronchography may be used to delineate the extent of a central tumour. The tumour may rarely metastasize to nodes and liver, but more commonly invades local structures widely.

### Treatment and prognosis

Ideally, treatment is by excision, although owing to the usually central situation of the tumour this may not be feasible. In some centres, tracheal reconstruction procedures have allowed complete removal [107]. If resection proves impossible, radiotherapy often produces prolonged remission and relief of symptoms where tracheal obstruction is threatening life [108]. The use of laser therapy holds promise of controlling the obstruction if resection is

**Fig. 42.11** Resected bronchial tumour showing bronchial lumen compressed from both sides by infiltrating submucosal adenoid cystic carcinoma (haematoxylin & eosin  $\times 150$ ).

impossible. The tumour grows slowly, but nevertheless has a considerably worse prognosis than carcinoid [109,110].

### **Mucoepidermoid tumour**

These salivary gland-type tumours are even less common than cylindromas, which they resemble in clinical features [106,111–113]. They may occur at any age, and like all slow-growing intrabronchial tumours may initially be misdiagnosed as asthma [114]. Pathologically they may be divided into high-grade and low-grade types, the former having a greater propensity to metastasize and invade locally. They arise from glandular structures, usually in trachea and major bronchi, and histologically consist of squamous elements and mucus-secreting acini. A papillary variant has been described [115]. Treatment is by surgical resection if possible [113,116].

### **Bronchial melanoma**

Malignant melanomas may metastasize to bronchi but more commonly to lung parenchyma. Very rarely, primary melanoma arises in bronchi where it is usually clinically indistinguishable from bronchial carcinoma [117], although pigmentation may be seen bronchoscopically or on sputum cytology [118]. The prognosis is poor, metastasis occurring to local nodes and by haematogenous dissemination; nevertheless, long-term survival has been reported following pneumonectomy [119]. The origin of the tumour is presumed to be from neuroectodermal melanoblasts that have migrated to the bronchial mucosa during embryonic development, since melanocytes are not a normal feature of the respiratory epithelium.

### **Bronchial papilloma**

Papillomas are quite frequently seen on the larynx, but are rare tumours of trachea and bronchi. They may occur as solitary lesions [120,121] or as multiple tracheobronchial papillomatosis [122]. The latter seem to occur predominantly in middle-aged men. All papillomas should be regarded as having the potential to undergo malignant change to squamous carcinoma [123] and should be excised. Histologically they resemble papillomas elsewhere, with a vascular stroma surrounded by stratified keratinizing squamous epithelium. They are not to be confused with inflammatory polyps that may sometimes be seen in bronchiectasis or asthma [124].

### **Clear-cell tumour**

This benign tumour is composed of sheets of cells with small nuclei and foamy or clear cytoplasm [125,126]. It usually appears as a small peripheral nodule on chest radiography. The cell of origin is not known and it has not been described as undergoing malignant change. It is not to be confused with metastatic renal carcinoma or with the clear-cell subdivision of large-cell anaplastic bronchial carcinoma.

### **True bronchial adenoma**

Benign adenomas, which may occur at any age, may arise from several different cells in bronchial glands [127]. All are exceedingly rare. Mucous gland [128], serous [129], pleomorphic (derived from myoepithelial cells) [130], oncocyctic (from a cell in the region of the collecting ducts) [131] and mixed cell types have been described. Diagnosis

is normally made after excision, which would be expected to be curative.

### **Sclerosing pneumocytoma (sclerosing haemangioma)**

This peripheral tumour occurs predominantly in women and may present at any age. It is usually small, subpleural and polypoid and may be associated with cough, haemoptysis or no symptoms [132,133]. It seems more common in Chinese women, and electron microscope studies have suggested that it is not a tumour of endothelial cells but of type II pneumocytes [134]. Malignant change has not been described.

## **Tumours of vascular tissue**

A group of rare tumours originate in vascular tissue, including capillary haemangioma and haemangiomatosis [135], haemangiopericytoma, intravascular bronchioloalveolar tumour and angiosarcoma. Sclerosing haemangioma seems to be derived from type II epithelial cells in a number of cases (see above), although variants have been thought to be of endothelial origin [134]. Two non-neoplastic vascular anomalies, arteriovenous malformation and pulmonary telangiectasia, are discussed here for convenience, as are tumours arising from lymphatic tissue.

### **Haemangiopericytoma**

This tumour arises from capillary pericytes, pluripotential cells associated with the vascular basement membrane [136]. It presents as a peripheral radiographic shadow, which may be very large and involve a whole lobe. Growth rate is very variable and it may both metastasize widely and invade locally. However, removal of a small or early lesion may be curative; if this is not possible, radiotherapy may be effective. Similar tumours may occur in other organs of the body.

### **Intravascular bronchioloalveolar tumour**

This is a multicentric lung tumour that arises in either vascular pericytes or endothelial cells and which is more common in women [137,138]. It may occur at any age, half the reported tumours having presented before the age of 40. It is usually found incidentally on chest radiography, when it appears as multiple small nodules, but may present in a form that mimics pulmonary embolic disease with pulmonary hypertension [139]. Excision of these tumours shows collections of vesicular cells with nodules of eosinophilic hyaline material. The cells protrude into alveoli and bronchioles and invade arteries and veins. There is often central necrosis. Metastasis occurs occasion-

ally, but the course of the disease is usually characterized by slow extension of the tumour throughout the lungs until the patient dies in respiratory failure. No treatment has so far been shown to induce remission, although transplantation would presumably be an option.

### **Angiosarcoma (Kaposi's sarcoma)**

This malignant tumour is derived from vascular endothelium [140]. Its cells secrete multiple cytokines that probably sustain the tumour's growth. It was very rarely recognized in the lung prior to the arrival of AIDS in the USA but now appears commonly in subjects with sexually acquired disease; however, it is still rare in those in whom AIDS was acquired through blood transfusion or intravenous drug abuse, suggesting that another infection together with immunosuppression is necessary for its pathogenesis. Recently a new herpes virus has been found in a proportion of these tumours [141]. Previously it was more familiar as a rather indolent skin tumour in Africans [142] or occasionally as a more aggressive disseminated disease [143]. Now, however, its most frequent presentation is in people suffering from AIDS [144], in one series being present in the skin at death in 59% of patients and in the lungs in 36% [145]. The tumour presents with diffuse nodular and patchy infiltrates throughout both lungs [146,147] (Fig. 42.12); the patient has often been unwell for some time previously and may have generalized lymphadenopathy. The radiograph shows gradually increasing diffuse nodular infiltrates that have a tendency to coalesce and become more profuse over several months, although the disease may be present with a normal radiograph [148,149]. Pleural involvement with effusion may occur. The diagnosis may be made by transbronchial [150] or open lung [144] biopsy, though until there is reasonably effective treatment for the tumour the latter procedure is rarely justified. However, there is therapeutic justification for the use of bronchoscopy for differentiating Kaposi's sarcoma from other diffuse infiltrative conditions that afflict AIDS sufferers, and future treatment possibilities, such as the use of combination chemotherapy, interferon  $\alpha$  or liposomal agents [151–153], may make aggressive diagnostic procedures more worth while (see Chapter 52).

The pathological appearances are of multiple discrete haemorrhagic nodules throughout the lung parenchyma. Bronchi and vessels may be invaded. Histological appearances vary from thin fibrous septa with malignant epithelium in a lake of blood to solid sheets of spindle cells with inconspicuous vascular spaces [146] (Fig. 42.13).

Many combinations of antiviral and chemotherapeutic agents have been tried and temporary remission may be obtained [152,153]; the use of liposomal drug preparations to deliver adequate doses with minimal side-effects seems a promising approach. However, no regimen has been shown to be sufficiently effective and free of toxicity to

**Fig. 42.12** Radiograph of African patient with AIDS and extensive pulmonary infiltration by Kaposi's sarcoma. (Courtesy of Dr Dwight McLeod.)

**Fig. 42.13** Histological appearance of Kaposi's sarcoma showing ectatic vascular channels admixed with malignant spindle cells, infiltrating connective tissue stroma (haematoxylin & eosin  $\times 150$ ).

become established treatment, and usually the patient passes from having no respiratory symptoms to death from respiratory failure over the course of a few months.

### **Lymphangioliomyoma**

This is a condition affecting women [154–156], almost always of child-bearing age, though occasional cases have been described after the menopause [157]. The patient often presents initially with haemoptysis, pneumothorax and a chylous pleural effusion. Initially the chest radio-

graph may be normal, but subsequently there is often a fine reticulonodular shadowing, sometimes associated with septal lines. The changes are more marked at the bases and are seldom profuse. In addition, or sometimes alternatively, there is evidence of overinflation or frank emphysema and this combination in a premenopausal woman should always raise the possibility of lymphangioliomyomatosis. The patient may often have other manifestations of systemic disease, such as lymphoedema and leiomyomas of kidney or uterus.

Unlike many conditions where the radiograph shows a

fine infiltrate, lung function testing usually shows an obstructive pattern and hyperinflation. Sometimes there may be a considerably higher thoracic gas volume (measured by plethysmography) than total lung capacity (measured by helium dilution); this probably represents air trapped in cysts by peribronchiolar muscle hypertrophy.

It is easy to miss the diagnosis of lymphangioleiomyomatosis because of the way it mimics emphysema. Chylous effusion and recurrent pneumothorax are clues, as is irreversible airways obstruction in a non-smoking woman. Lung biopsy shows the characteristic histology [158,159]; the lungs show diffuse cystic change with apparent intervening fibrosis. Microscopically, there is proliferation of spindle-shaped primitive smooth muscle cells around lymphatics throughout the lungs and pleura (Fig. 42.14). The airways obstruction is probably related to smooth muscle proliferation around bronchioles, leading

to air trapping and cyst formation. Rupture of these cysts causes pneumothorax, while haemoptysis is probably explained by capillary congestion due to perivenular muscle hypertrophy.

The course of the disease is one of progressive increase in dyspnoea over about 10 years, culminating in death from respiratory failure. In postmenopausal women it may be more slowly progressive, suggesting that it is hormone-dependent [157]; indeed progesterone and oestrogen receptors have been demonstrated on lung biopsy material [160]. The condition may deteriorate in response to oral contraceptives, and remit or progress less rapidly after oophorectomy [161] or treatment with progesterone [162]. Because of this hormone dependence, it has been suggested that the use of oral contraceptives may be an aetiological factor, although a case-control study has not supported this hypothesis [163]. If the diagnosis is

(a)

(b)

**Fig. 42.14** Necropsy specimen from lung of a woman who died apparently of emphysema but who proved to have lymphangioleiomyoma. (a) Dilated airspaces with proliferating smooth muscle in remaining alveolar walls (haematoxylin & eosin  $\times 50$ ). (b) A higher-power view showing the proliferating smooth muscle cells (haematoxylin & eosin  $\times 150$ ).

made in life, progesterone or oophorectomy would be appropriate treatment, especially if instituted at an early stage of the condition, and lung transplantation would now be an option.

### **Tuberous sclerosis**

This inherited disorder usually presents with mental retardation or slowly progressive dementia, associated with epilepsy and skin changes comprising patchy depigmentation, warty elevations on the face (adenoma sebaceum) and patches of elevated rough yellowish skin on the back (shagreen patch) [164]. It affects males and females equally. It may be associated with a nodular infiltrate on chest radiography that leads to cystic change. Pathologically the lesions are multiple leiomyomas, though probably based on blood vessels rather than lymphatics. Similar smooth muscle tumours are found in other organs. Sometimes the tumours are described as being angiomyolipomas, and this lesion has also been described in the lung in the absence of other evidence of tuberous sclerosis [165]. The pulmonary condition may be complicated by recurrent pneumothorax [166] or by pleural effusion [167]. The pathological condition overlaps with that of lymphangiioleiomyomatosis and airflow obstruction with reduced diffusing capacity are physiological features also [168]. In view of this, hormonal treatment has been tried in female patients with some limited evidence of response.

### **Arteriovenous malformations and telangiectasia**

(see also Chapter 50)

These lesions represent a developmental anomaly rather than a tumour and consist of abnormal connections between pulmonary artery and vein, probably due to persistence of the short fetal capillary anastomoses. Pathologically they appear as a thin-walled labyrinth of vessels connecting a rather dilated artery and vein [169,170]. Occasionally they may be supplied by more than one artery and there may be associated anomalies of pulmonary venous drainage.

#### **Clinical features**

Patients with this condition may present with one or several rounded radiological opacities [171]. In some cases there may be a fine diffuse nodularity of the lower zones, when the condition is known as pulmonary telangiectasia [172,173]. Discrete lesions, which may be single or multiple, are not necessarily associated with symptoms or signs [174]; the presence of these depends on the size of the shunt. If it is large, finger clubbing and cyanosis may be apparent and a systolic bruit, sometimes accentuated by inspiration, may be heard over the lesion [175]. In up to

half of all cases, evidence of hereditary telangiectasia (Osler-Weber-Rendu disease) elsewhere may be present [176], the patient having had nose or gastrointestinal bleeds and showing small telangiectases on tongue, face and lips (see Fig. 50.14). In pulmonary telangiectasia, the patient presents with cyanosis, finger clubbing and increasing breathlessness [172]. Faints or fits due to cerebral hypoxaemia may occur.

The discrete type of arteriovenous malformation may present at almost any age but is most frequent in the third decade and after. Telangiectasia is more frequently seen in young children, since it always causes cyanosis and symptoms, although the diagnosis may not be made until adult life. The radiological appearances of the discrete lesions are of rounded or lobulated shadows, usually in lower zones. The feeding and draining vessels may be apparent on the radiograph; if not, they can usually be demonstrated by tomography (Fig. 42.15). They gradually increase in size over several years. The diagnosis should be confirmed by pulmonary angiography, especially if removal is planned, as smaller lesions not seen on chest radiography may then become apparent [171]. Pulmonary hypertension is not normally present, because of low vascular resistance, but has been described [177]. In pulmonary telangiectasia the chest radiograph shows a diffuse lower zone nodularity that may be easily mistaken for pulmonary fibrosis (Fig. 42.16). The associated marked cyanosis and relative lack of breathlessness (relative to that of a patient with cyanosis at rest with pulmonary fibrosis) should alert the physician to the correct diagnosis. The nodular shadows may be quite small but tend to increase in size as time goes by. Pulmonary angiography demonstrates the lesions if they are large enough, although minute ones may not be seen.

The only physiological abnormality in patients with the discrete lesions may be slight hypoxaemia and failure of the arterial blood fully to saturate on breathing oxygen. With multiple lesions, a low carbon monoxide diffusing capacity is usual, due to diversion of blood from the pulmonary capillary bed. Paradoxically, in diffuse telangiectasia, breathing of 100% oxygen may lead to full saturation because oxygen is able to diffuse into the small abnormal vessels sufficiently rapidly [172]. On catheterization, dye curves do not show the two peaks of an intracardiac shunt but a decreased transit time with rapid reappearance of dye. Radiolabelled macroaggregates of albumin may be used to confirm the diagnosis in telangiectasia [173,178].

#### **Management and prognosis**

The solitary lesion should generally be removed [179,180], since the shunt increases progressively and complications such as brain abscess or bacterial infection of the angioma itself may occur. Before removal, angiography should be carried out to look for additional smaller lesions. Even if

**Fig. 42.15** (a) Penetrated film showing arteriovenous malformation in right lower lobe, in cardiophrenic angle. (b) Pulmonary arteriogram of the same patient.

these are undetected, there is a risk that other shunts may gradually become apparent after the operation and these in turn may need removal [172]. For this reason, surgery should if possible avoid resection of lung. If the lesions are multiple, as is the case in about 20% of patients, it may not be practicable to remove them and in such patients embolization with detachable balloons or coils passed through a catheter is now the treatment of choice (see Chapter 50) [172]. In the absence of such treatment these patients become progressively more cyanosed and breathless, eventually dying of the effects of hypoxaemia and high-output cardiac failure. Transplantation may be necessary in patients with telangiectasia [181]. While most such patients do not survive their fourth decade, the author has made the diagnosis for the first time in a patient of 58 whose symptoms dated back to childhood [182].

#### **Pulmonary capillary haemangiomatosis**

This is an exceedingly rare locally invasive tumour pre-

sented with progressive pulmonary hypertension, characterized pathologically by proliferation of thin-walled capillaries throughout the lungs [183]. It is progressive and fatal unless transplantation can be carried out.

#### **Pulmonary lymphangiectasis**

Primary cystic dilatation of pulmonary lymphatics may occur in children, either as part of a generalized disease of lymphatics or as a lesion confined to the lungs [184,185]. It may occur throughout the lungs, presenting as multiple cystic shadows on chest radiography, or be localized to one or several lobes. In this latter case, it may present as a hilar or intrapulmonary solid shadow or may mimic bronchiectasis. After surgical removal it can be seen to consist of dilated very thin-walled cysts filled with lymph. The cysts are adjacent to bronchi, veins, pleura and in interlobar septa and represent grossly dilated lymphatics. The cause of this congenital abnormality is not known.

#### **Pulmonary lymphangiomatosis**

This condition, analogous to capillary haemangiomatosis but characterized by overgrowth of anastomosing lymphatic vessels throughout the lungs, presents with breath-

**Fig. 42.16** (a) Chest film of right lower zone of cyanosed 58-year-old woman showing diffuse lower zone nodularity. (b) Angiogram of the same patient showing multiple minute arteriovenous malformations.

lessness in childhood, obstructive lung function, radiographic infiltrates and pleural effusions [186]. It runs a progressive course.

## **Tumours of muscle and connective tissue**

### **Leiomyoma and leiomyosarcoma**

The very rare leiomyoma originates in airway smooth muscle [187,188]. It may present as a peripheral tumour, when it has no specific features, or as a central bronchial or tracheal lesion, often polypoid or pedunculated. It tends to occur in children and young adults. Occasionally it has been removed by endoscopy [189], although surgical sleeve or wedge resection is to be preferred. Pathologically it consists of interlacing whorled smooth muscle cells and fibroblasts. On biopsy it may be difficult to distinguish from leiomyosarcoma, which is characterized by more mitotic figures and whose prognosis is related to the number of these [190]. Leiomyosarcomas present similarly

to benign leiomyomas, as incidental radiological findings when peripheral or with symptoms and signs of bronchial block when central. They may be removed surgically; in general, the larger they are at presentation, the worse the prognosis [190], although long-term cure has been reported in about 50% of cases after radical resection [187]. They appear not to be radiosensitive. Metastases occur and the prognosis is usually poor if the tumour cannot be resected. In assessing patients for surgery, care should be taken that the pulmonary tumour is not one of several metastases from a primary uterine sarcoma. Both leiomyoma and leiomyosarcoma have been reported in the trachea, presenting with signs of respiratory obstruction. They may be misdiagnosed as asthma. Resection with end-to-end tracheal anastomosis or with tracheal reconstruction with myocutaneous flaps has been associated with reported cures [191,192].

### **Rhabdomyosarcoma**

This rare tumour has been reported in bronchi, trachea and peripheral lung [193–195]. Its apparent striated muscle origin is presumably from either primitive pluripotential mesenchymal cells or displaced teratomatous muscle cells. It presents no specific clinical features and should be removed by radical resection where possible.

### **Fibroma and fibrosarcoma**

Benign fibroma of bronchus or lung is also an exceedingly rare tumour with no special clinical features [190,196]. Pleural fibroma, which is a benign mesothelioma, is discussed in Chapter 43. Fibrosarcoma has also been described, arising in bronchus, lung or pulmonary artery [197]. It may be difficult to distinguish pathologically from leiomyosarcoma.

### **Lipoma and liposarcoma**

Lipomas are very rare tumours that may occur in trachea or bronchi [198,199]. They may be pedunculated and produce obstruction or arise deep in the bronchial wall and present as radiological shadows. They consist of mature lipocytes surrounded by fibrous trabeculae. Liposarcoma is a highly malignant tumour, usually derived from soft tissues, and has been reported in the mediastinum [200], pericardium [201] and trachea [199] but not so far in bronchus. It commonly metastasizes to the lung from elsewhere. It may consist of a mixture of well-differentiated fat cells and poorly differentiated lipoblasts in a myxoid stroma, or of anaplastic bizarre giant cells with some lipoblastic differentiation. It invades locally and spreads by metastasis.

### **Other connective tissue tumours**

Other tumours have been described occasionally in the literature. These include benign chondromas [202], which may be confused with chondromatous hamartomas, chondrosarcomas [203] and myxoma [204]. Fibroma and myxoma may calcify.

Carney's triad is the name given to the coincidence of pulmonary fibromas, leiomyosarcoma of stomach and functioning paraganglionoma [205,206]. The lung lesions are benign, and may be single or multiple. If one is unaware of the syndrome, as is probably the case with most doctors, the lung lesions may be mistaken for metastases from the stomach. If the lung and stomach tumours are found, tests should be carried out for the third component, which may cause problems during anaesthesia. Removal of the stomach tumour, sometimes together with metastases, has been attended by prolonged remission so a radical surgical approach seems justified [207]. Patients have been described in whom only two of the three components of the triad have been found, and one patient where the sarcoma was in the duodenum [208]. The syndrome appears to occur predominantly in young females.

### **Tumours of neural tissue**

Neural tumours may be classified as neurilemmoma (arising from the Schwann cell), neurofibroma (from the

nerve sheath), ganglioneuroma (from the neurone) and their malignant counterparts neurosarcoma and neuroblastoma. Mixed forms occur and tumours may show transitional features between benign and malignant types; histopathological diagnosis may therefore be difficult. In addition, tumours may arise in paraganglion cells, i.e. pheochromocytoma and chemodectoma.

Neurilemmoma, neurofibroma and neurosarcoma are exceedingly rare tumours in the trachea and bronchi [209,210], though they are the commonest tumours of the posterior mediastinum (see Chapter 49). Neurofibroma may be seen as part of von Recklinghausen's syndrome of multiple neurofibromatosis. Chemodectomas or paragangliomas occur in the posterior mediastinum and may be responsible for causing hypertension [211]. They have been described occasionally as occurring within the lung in association with the pulmonary artery [212]. Multiple minute (0.2 cm) tumours, similar on light microscopy to chemodectomas, have been seen within the lung as an incidental finding at postmortem, although their significance and histogenesis is unclear [213].

## **Tumours of mixed-cell origin**

### **Teratoma**

Intrathoracic teratomas are usually seen in the mediastinum (see Chapter 49). They are tumours derived from the three primitive germ layers and may contain a variety of tissues, including hair, skin, bone, muscle and teeth. Glandular tissue may actively secrete hormones. The benign type is often called a dermoid cyst. Malignant change occurs in up to 20% of teratomas, when one or more cell lines show poor differentiation and pleomorphism. Often trophoblastic tissue is predominant, the tumour taking on the characteristics of a choriocarcinoma.

Both benign and malignant teratomas have been described in the lung and, very occasionally, in the bronchus [214,215]. Their clinical characteristics are those of any slow-growing pulmonary tumour [216], with the additional possibilities of complications such as necrosis due to pancreatic hormone secretion or expectoration of components such as hair. Because of their potential for malignant change, and also because diagnosis is rarely made before excision, treatment is surgical removal. Malignant tumours in the mediastinum have also shown good response to chemotherapy in combination with surgery [217].

### **Hamartoma**

Hamartoma has usually been regarded as a developmental anomaly [218–221]; however, recent genetic analysis of a series of such lesions has shown an abnormal karyotype, suggesting that they are neoplastic [222]. It is a lesion in

which the normal components of the organ are combined in a disorganized manner. Pathologically, pulmonary hamartomas are usually small 1–3 cm lesions containing predominantly cartilage, with epithelium, fibrous tissue and fat. Calcification occurs frequently and on radiography they appear as well-demarcated, dense, round peripheral shadows often with a central dot of calcium (Fig. 42.17). Though usually single, multiple hamartomas may occur and give rise to diagnostic difficulties [223]. Multiple lesions may also be a feature of tuberous sclerosis and have been described in the trachea as an incidental finding at autopsy [224]. Cystic appearances may be due to deposits of fat within the lesion [225], and multiple cavitating tumours have been described that mimic metastases [226]. They may grow slowly and very occasionally reach a large size. They occur predominantly in the fourth decade, although they may be seen at any age, and are more common in males than females [219,227].

Less commonly, the predominant tissue in a hamartoma is smooth muscle [225,228,229]. These fibroleiomyomatous hamartomas may occur as a diffuse pulmonary infiltrate, giving the appearance of honeycomb lung, or as a localized lesion; the latter usually presents radiologically as an ill-defined subpleural shadow. The tumour may be intrabronchial, giving rise to collapse or distal infection. In

contrast to the chondromatous type, fibroleiomyomatous hamartomas are more common in women [220].

If a hamartoma is diagnosed with confidence, on the basis of its presence on old radiographs, slow growth and central calcification, the patient may be spared surgery since malignant change has been described only rarely [230]. Indeed there is some doubt that it ever occurs in true hamartomas [1]. More usually, however, there is sufficient clinical doubt for surgery to be justified; the tumour has a characteristic hard feel and can often be removed without resection of lung tissue. The finding of a fibromatous hamartoma should bring to mind the possibility of Carney's triad; in one series of 65 resections this was found in two, while in eight an associated carcinoma was found [231].

### Carcinosarcoma and blastoma

These tumours contain malignant cells derived from both epithelial and connective tissue [232,233]. Their histogenesis is obscure. Blastomas are regarded as tumours that contain cells of fetal type, whereas carcinosarcomas are derived from adult cells. In children the tumour is regarded as highly malignant but responsive, at least in the short term, to combination chemotherapy [234,235]. Their histological features are of interest to pathologists

**Fig. 42.17** Typical smoothly outlined, dense, spherical appearance of hamartoma.

[236], while from a clinical point of view they behave like other bronchial carcinomas; metastasis occurs and may be of single or both cell types. Treatment is by surgery if possible, usually combined with chemotherapy.

### Metastatic tumours in the lung

Any malignant tumour, including bronchial carcinoma, may metastasize to the lung. Clinically, it is helpful to recognize several different patterns of metastasis, as this may be of assistance in differential diagnosis or planning treatment. These patterns include solitary metastasis, multiple cannonball lesions, diffuse nodular infiltration, lymphangitic carcinomatosis, endobronchial metastasis and carcinomatous embolization. Metastasis to hilar nodes bilaterally may also be seen.

#### Solitary metastasis

This lesion presents as a peripheral tumour, usually spherical and well demarcated from surrounding lung [237]. It may cavitate and clinical differentiation from primary tumour is difficult, especially as it may be the presenting feature of an occult neoplasm elsewhere. The most common sites of origin of the tumour are large bowel, breast, cervix, kidney and sarcomas. In the absence of metastases elsewhere, and if the primary tumour is

resectable, there may be a case for surgical removal [237,238], although it is never certain whether reported long-term survival following this procedure owes more to the surgery or the biological nature of the tumour. Other tumours may respond to radiotherapy or chemotherapy.

#### Multiple cannonball tumours

Multiple spherical lesions of many different sizes are characteristic of metastatic deposits (Fig. 42.18), though similar appearances may occur occasionally in sarcoidosis, tuberculosis, hydatid and fungal disease, multiple hamartomas and Wegener's granulomatosis. Cannonball metastases originate particularly from hypernephroma, seminoma, sarcoma, colon carcinoma, choriocarcinoma and breast carcinoma. Cavitation, calcification or haemorrhage may occasionally occur in these metastases; when necrosis occurs in them adjacent to pleura, they may cause pneumothorax. It is not normally necessary to take further diagnostic steps, since the primary tumour is usually clinically evident. If it is not, care should be taken to exclude seminoma, and prostatic and breast carcinoma, which may respond to appropriate combinations of chemotherapy, hormone treatment and radiotherapy. In patients where there is no obvious primary tumour, biopsy of a lesion is justified in order to exclude rare granulomatous and infective causes.

**Fig. 42.18** Multiple cannonball metastases from oesophageal carcinoma. Note the oesophageal tube.

### Diffuse nodular infiltration

Multiple small nodules, usually less than 5 mm in size but varying from pin-point size upwards (Fig. 42.19), occasionally occur as a manifestation of metastatic spread, particularly from breast, stomach, thyroid and colonic carcinomas. A similar appearance may occur in diffuse alveolar cell or pulmonary adenocarcinoma. The patient may present with shortness of breath, although this is initially not so severe as with lymphangitic spread. Again, it is desirable to exclude those primary sites that may be responsive to chemotherapy or hormone treatment. Spontaneous regression after removal of the primary tumour or temporary regression after corticosteroid treatment may occur very occasionally.

### Lymphangitic carcinomatosis

Lymphangitic spread of carcinoma occurs particularly from breast, stomach, pancreas and prostate, as well as from bronchial carcinoma itself. The patient presents with increasingly severe dyspnoea, cough and evidence of general ill-health. Auscultation of the lungs may be normal or show repetitive inspiratory crackles. The radiograph shows multiple small nodular and linear shadows and Kerley's lines, particularly in the lower zones (Fig. 42.20). The course is usually rapidly downhill, though

remission has been described with chemosensitive or hormone-dependent tumours [239]. Partial relief of symptoms may occur on treatment with corticosteroids, diazepam or opiates.

### Endobronchial metastases

Endobronchial metastasis is much less common than the patterns described above. It occurs particularly in breast, kidney, colon and cervical cancer [240]. In its mode of presentation it mimics primary bronchial carcinoma [241,242] and most cases described in the literature are of patients subjected to lobectomy or pneumonectomy on this account. The finding of clear-cell tumour on bronchial biopsy or cytology should always arouse suspicion of a renal primary. Indeed, endobronchial renal metastases may be expectorated by the patient [242]. The prognosis depends on the biological behaviour of the tumour, although long-term survival with or without resection may occasionally occur.

### Carcinomatous embolization

Very rarely a patient may present with increasing dyspnoea, a clear chest radiograph and reduction in  $PaO_2$  and diffusing capacity. In such circumstances, multiple pulmonary emboli should be considered; occasionally these

**Fig. 42.19** Diffuse fine nodular infiltrate due to metastatic breast adenocarcinoma.

**Fig. 42.20** Lymphangitic spread of breast carcinoma. Note irregular pulmonary infiltration and Kerley B lines.

are due to blood-borne tumour cells rather than thrombi. This syndrome has been described with prostatic, breast, stomach, colonic, pancreatic, hepatic and cervical cancers and with choriocarcinoma [243,244]. The lung scan shows features typical of multiple emboli. The diagnosis is usually made at postmortem, but would probably require open lung biopsy in life.

### Bilateral hilar node metastasis

The common causes of bilateral hilar node enlargement are sarcoidosis, tuberculosis in Asians, and lymphoma. Oat-cell carcinoma of bronchus may metastasize bilaterally, and this may also be an occasional feature of cancers of kidney, head and neck, testicle and breast, and of malignant melanoma [245,246].

# DISEASES OF THE PLEURA

ANTHONY SEATON

The two layers of the pleura (visceral and parietal) that surround the lung are described in Chapter 1. Only the parietal layer has a somatic nerve supply, derived from intercostal and diaphragmatic nerves, and is therefore sensitive to painful stimuli. In almost all instances of disease of the pleural membranes and of the potential cavity that they enclose, the cause is in the lung or elsewhere in the body, although in a few instances primary pleural disease may occur. This chapter discusses the main diseases that affect the pleura, with the exception of empyema (see Chapter 14) and pneumothorax (see Chapter 44).

## Physiology of the pleura

The pleura transmits the force generated by the respiratory muscles to the lungs [1]. During normal respiration there is therefore a pressure negative to atmosphere (about  $-0.66$  kPa at functional residual capacity) within the pleural space. This would tend to suck capillary fluid and gas from surrounding tissue into the space if it were not for other balancing factors. In the case of fluid, there is a hydrostatic pressure difference between parietal pleural capillaries, supplied by systemic arterial vessels (about 4 kPa), and visceral pleural capillaries, supplied by pulmonary arterial vessels (about 1.5 kPa). Plasma oncotic pressure is the same in both sets of capillaries (about 4.66 kPa), while pleural osmotic pressure is only about 0.8 kPa, since little protein is able to escape from the adjacent healthy capillaries. Thus there is a net force that drives fluid from parietal capillaries to pleural space ( $-0.66 - 4 - 0.8 + 4.66 = -0.8$  kPa); similarly, a net force drives pleural fluid into visceral capillaries and lymphatics ( $-0.66 - 1.5 - 0.8 + 4.66 = +1.7$  kPa). There is therefore a regular transfer of low-protein fluid from parietal to pleural space, although recent evidence suggests that reabsorption is not, as was thought, via the visceral pleura but through lymphatic vessels opening into the parietal pleura. In the case of gas, any that gains access to the pleural space is at atmospheric minus pleural pressure, i.e.

$101.1 - 0.66 = 100.44$  kPa. In contrast, the partial pressure of gas within the pleural capillary blood is some 5.3–6.6 kPa below atmospheric pressure, and thus there is a driving force of about 5.3 kPa available to resolve any pneumothorax.

The pleural fluid is in a dynamic state, 30–75% of the water being turned over every hour [2]. This is accelerated by increased lung movements, such as during exercise. Protein and particles are turned over much less rapidly, being absorbed by lymphatics only [3,4]; stomata leading into lymphatics have been demonstrated over the lower mediastinal, chest wall and diaphragmatic parietal pleura [5]. These, together with the valves of the lymphatic vessels, ensure transport of protein and particle-containing fluid from the pleural space. Any disease that causes inflammatory or neoplastic change in the parietal pleura is likely to decrease protein reabsorption and therefore alter the fluid hydrodynamics in such a way as to increase the size of the effusion.

It has generally been assumed that the pleural space is lubricated by a thin film of serous fluid, and it has been shown that a few millilitres of this fluid can be obtained from the normal space. However, it has been suggested on physical grounds that this would be unlikely to provide adequate lubrication and that a surfactant would be more efficient; such surface-active phospholipids have been identified in pleural fluid [6].

## Dry or fibrinous pleurisy

### Clinical features

Pleural pain is characteristically sharp and associated with inspiration, coughing and movements of the chest wall. When it is severe the patient breathes in short grunts and may attempt to splint the appropriate part of the chest by holding it or lying on it. The site of pain can usually be localized quite closely and is most frequently in the lower posterolateral parts of the chest. As the pleurisy improves, or sometimes from the beginning when the upper chest is

involved, the pain may be more of an ache though still associated with movement and breathing.

The diagnostic sign of pleurisy is a rub, of a creaking superficial nature, usually localized closely to the site of the pain. At its most marked this is unmistakable and heard in inspiration and expiration; however, it may be confined to part of the inspiratory cycle and at times may be difficult to distinguish from pulmonary crackles. As the pleurisy improves, it tends to become less obvious but may persist after the pain has gone and in occasional patients a loud rub may be present indefinitely. Indeed, pleural rub may sometimes be heard in patients with no pain and pleural pain may occasionally occur without a rub.

Because of the innervation of the pleura, pleuritic pain may be referred to the shoulder tip via the phrenic nerve when the area over the central tendon of the diaphragm is involved or to the upper abdomen when the area over the peripheral diaphragm is affected. In the latter case this may cause diagnostic difficulties unless the relationship to respiration is recognized, especially as a rub is usually not audible. The pain of pleurisy is due to inflammation of the parietal pleura and is presumably provoked by stretching. The rub arises from friction between the two pleural surfaces when their normal lubricating mechanism is impaired by the inflammatory exudate.

### Causes

Dry pleurisy may be due to chest trauma, usually associated with rib fracture. Apart from this, the most common cause is infection of the underlying lung; recurrent pleurisy is usually associated with recurrent infection of bronchiectatic lung. Bornholm disease, collagen diseases (especially rheumatoid and systemic lupus) and pulmonary infarction are other not infrequent causes. Tumours invading the chest usually cause a persistent, continuous pain but may occasionally present with pleurisy. Rarely dry pleurisy may be associated with asbestos exposure (see below), tuberculosis and subdiaphragmatic abscess.

### Bornholm disease

Bornholm disease is named after the Danish island where an early epidemic was described and is also known as epidemic pleurodynia, epidemic myalgia or, colloquially, the devil's grip [7]. It is caused by an enterovirus, usually Coxsackie B but occasionally Coxsackie A or an echovirus [8]. In one study of an outbreak in an American football team it has been suggested that spread may have been due to contamination of a common drinking source by one of the players [9]. It has a short incubation period (3–5 days) and may occur in late summer and autumn epidemics, although sporadic cases are frequent. The disease is most

common in children and young adults, usually starting with fever and upper respiratory symptoms followed by the characteristic pain. Typically this occurs in the chest or upper abdomen and may be very severe. It is worsened by movement and respiration and associated with tenderness of intercostal muscles. Pleurisy, sometimes referred to the shoulder, is common and a pleural rub is sometimes audible. Pericarditis with rub may also be present. Fever and a raised erythrocyte sedimentation rate are occasionally present at this stage but there are no characteristic haematological changes. The chest radiograph is usually normal, though a blunted costophrenic angle may be present. There may be diagnostic confusion with early herpes zoster and the eosinophilia–myalgia syndrome associated with L-tryptophan therapy.

The illness usually lasts about a week, the pain gradually subsiding. Other organs, such as the heart, central nervous system or testes, may occasionally be involved, resulting in a more prolonged course. The disease has a tendency to relapse, usually in a milder form, over several weeks. The diagnosis is made from the characteristic clinical features and may be confirmed by viral culture of stools or throat swabs and by a rise in the appropriate viral antibodies. There is no specific treatment but analgesics are often needed to control the pain.

### Recurrent polyserositis

This condition, also known as periodic disease or familial Mediterranean fever, is an autosomal recessive genetic disease afflicting predominantly people of Jewish, Arabic, Armenian and Turkish origins [10,11]. The genetic defect has been shown in several families to be on the short arm of chromosome 16 [12,13], although the biochemical defect remains unknown. The disease is characterized by recurrent fever and inflammation of serous membranes. Attacks occur at irregular intervals, from several days to several years. The disease almost always manifests itself in childhood and very rarely after the age of 40, and there is often a history of similar illness in other members of the family, especially siblings. It presents most commonly with peritoneal inflammation that mimics a ruptured appendix, and the patient has often been subjected to laparotomy. Pleurisy mimicking Bornholm disease is another common presentation, as is acute inflammation of one or two large joints. The pain is accompanied by fever, tachycardia and often chills, and there is often a moderate neutrophil leucocytosis during attacks. Effusions into large joints and erysipelas-like rashes on the legs may occur. A similar periodic syndrome associated with hyperimmunoglobulinaemia D has been described in European families in which prolonged myositis is more frequent and serositis and amyloidosis rarer [14]. There is no diagnostic test, though immunological changes such as circulating immune complexes and raised immunoglobulins have

been described; amyloidosis of the kidneys is the most serious complication, occurring in 0–20% in different series, and may lead to renal failure. Acute attacks of the syndrome resolve spontaneously within 12–48 h in almost all cases, and apart from the renal complication the condition is generally regarded as having a benign course.

Treatment of the acute attack relies on the use of analgesics. Recurrent episodes may be prevented by regular use of colchicine [15] and there is some anecdotal evidence that this may help to prevent the long-term renal complication of amyloidosis [16].

### Diagnosis and management

The pain of pleurisy needs to be differentiated from that due to chest wall causes, such as rib fracture, intercostal muscle pain and Tietze's syndrome, and that due to neurogenic causes, such as herpes zoster and root compression. The presence of a pleural rub is helpful, although this may be heard sometimes following rib fractures. A chest radiograph is frequently useful in showing the primary lung condition. If this is normal, or if it only shows a small amount of fluid in the costophrenic angle, it is important to consider the possibility of pulmonary embolism, and further examination of the legs together with isotopic scanning may help in coming to a therapeutic decision (see Chapter 25). If this diagnosis is considered unlikely, it is reasonable to treat the patient with adequate analgesics and await developments; in most such cases, the pleurisy settles within a week. Paired blood samples taken in the acute and convalescent phases may be tested for viral antibodies. When the chest film is abnormal, further investigation or treatment may be necessary; for example pneumonic change would indicate bacteriological investigation and antibiotic treatment, while evidence of bronchiectasis may lead to consideration for surgery if it is giving rise to recurrent episodes of infection and pleurisy.

The pain of pleurisy is usually controlled by simple analgesia and the patient adopting a comfortable posture (often lying on the affected side). Severe pain may require opiates, although dramatic relief may often be obtained by raising intradermal wheals of local anaesthetic in four or five places around the site of maximum pain. This relief is often prolonged and the procedure, if successful, may be repeated periodically; it is particularly useful when the patient's respiratory condition makes the use of opiates inadvisable.

## Pleural effusion

### Clinical features

The effects of accumulation of fluid in the pleural space depend on the cause and on the amount of fluid. Small

effusions are often symptomless; even very large effusions, if they accumulate slowly, may cause little or no discomfort to the patient. If the effusion is due to inflammatory disease, it often starts with pleuritic pain that may be relieved as the fluid accumulates. The usual symptom of a large effusion is shortness of breath, often accompanied by a dull ache on the affected side; this is especially likely if the effusion is due to malignant disease of the pleura. Recurrent dry cough is frequently present, especially if the fluid has accumulated quickly.

The findings on physical examination are also dependent on the size and site of the effusion. Since most effusions are in the dependent part of the pleural space, the signs of diminished movements, dull percussion note and distant or absent breath sounds are found here. Bronchial breath sounds or aegophony (a nasal or bleating quality of transmitted voice sounds) may be heard immediately above an effusion. Large effusions displace the mediastinum to the opposite side unless there is underlying pulmonary collapse or associated pleural fibrosis. Although the signs of a large effusion are very characteristic, those of a smaller one may be mimicked by lobar collapse, pleural tumour or pleural fibrosis, and it is often difficult to assess the presence or absence of collapse or consolidation beneath an effusion. Careful clinical examination of the mediastinal position may help, as may asking the patient to change position in order to test whether the effusion moves.

### Radiological features

Free pleural fluid in small amounts (about 100 mL) may be seen as blunting of the costophrenic angle on posteroanterior or lateral films. Larger effusions are most dense at the base, obscure the diaphragm and show decreasing density towards the top. As the fluid rides up around the edges of the lung, attenuation of the X-rays decreases and the radiographic appearances suggest that the effusion is higher in the axilla than anteriorly or posteriorly (Fig. 43.1). However lateral films show the level to appear higher posteriorly and anteriorly, indicating that in fact the top of the effusion is horizontal, only showing radiographically where the X-rays have to traverse sufficient depth of fluid [17]. If there is doubt about the presence of fluid radiographically, a lateral decubitus film may be taken to show the shift of the effusion to the mediastinum or lateral chest wall. This may help particularly in differentiating a small effusion from pleural thickening.

Sometimes effusions may be encysted and cause diagnostic difficulties. Interlobar effusions may mimic tumour (Fig. 43.2); they occur particularly in cardiac failure and their clearance following diuretic treatment has given rise to the term 'vanishing pulmonary tumour' [18]. Subpulmonary effusions may not appear to rise into the axilla and may look like an elevated diaphragm. On the left, the

**Fig. 43.1** Chest film showing left pleural effusion.

stomach air bubble allows the distinction to be made, but on the right it may be more difficult. A lateral decubitus film or ultrasound investigation may be necessary. Other encysted effusions may occur anywhere in the pleural space, especially following pleural infection or pulmonary surgery, and may look like tumours. Serial radiographs often allow the diagnosis to be made and ultrasound may be helpful [19]. Fluid together with air (hydropneumothorax) shows the characteristic fluid level (Fig. 43.3). This appearance may be mimicked by fluid in a lung cyst or bulla, especially as hydropneumothorax may often be encysted following partial resolution of the pneumothorax.

### Causes

It is convenient to differentiate transudates from exudates when discussing the causes of pleural effusion.

### Pleural transudates

The causes of these are given in Table 43.1. By far the most common is congestive cardiac failure [20]; this effusion is often unilateral initially, usually on the right side. In severe failure it is usually bilateral, cardiac failure being the most frequent cause of bilateral effusions. The mechanism is increased transudation of fluid from the lung, partly as a result of increased capillary pressure but also because of increased pulmonary interstitial

**Table 43.1** Causes of pleural transudates.

Liver transplantation
<i>Increased capillary permeability</i>
Small pulmonary emboli
Myxoedema
<i>Obstructed lung lymphatics</i>
Lung transplantation

pressure [21]. The diagnosis is usually obvious from associated clinical features, this being one situation when diagnostic aspiration may be avoided, at least until after a trial of diuretic treatment. An important point

**Fig. 43.2** (a) Rounded right lower zone lesion in patient with congestive heart failure. (b) Lateral view shows the lesion to be fluid in the oblique fissure.

**Fig. 43.3** Right hydropneumothorax in patient with mesothelioma. The tumour can be seen under the ribs above the fluid level.

in radiological diagnosis is that bilateral effusions are rarely due to cardiac failure if the cardiac size is not increased (constrictive pericarditis being an exception), in which case other causes such as pulmonary embolism, neoplasm and occasionally hypoalbuminaemia need to be considered.

Pulmonary embolism may cause pleural transudates, although blood-staining occurs in about one-quarter of cases and exudates are found in about two-thirds [22]. Again, these effusions are often bilateral but usually quite small [23]. They may be associated with typical dome-shaped or linear (not, as is commonly believed, wedge-shaped) pulmonary shadows, although the radiological appearances are often quite non-specific and further investigations are usually necessary. Transudates due to hypoproteinaemia occur in cirrhosis, nephrotic syndrome and protein malnutrition. They may be diagnosed by their associated features. Constrictive pericarditis, due to old tuberculosis, rheumatoid disease or malignant infiltration of the pericardium, and constrictive cardiomyopathies are usually also associated with ascites; often this fluid tracks up into the right pleural space through small defects in the diaphragm [24,25], producing a large unilateral effusion. Indeed, a left-sided pleural effusion in hypoproteinaemia is usually due to some other cause and should be investigated accordingly. This same mechanism is responsible for the occasional right pleural effusion occurring during peritoneal dialysis [26].

Meigs' syndrome is the rare association of a benign ovarian fibroma with ascites and accompanying, usually right-sided, pleural effusion [27]. In fact ovarian fibroma is rarely associated with serous transudates and the finding of effusions in association with ovarian disease usually leads to the realization that they are exudates and that the tumour is malignant. In Meigs' syndrome it is likely that the pleural effusion has tracked through the diaphragm from the peritoneum.

Finally, myxoedema may cause pleural effusion, either as a consequence of ascites or pericardial effusion or, very rarely, as a direct effect on pleural capillary permeability [28]. This condition responds to replacement thyroxine therapy; the metabolic basis of the alteration in permeability of the capillaries of the serous membranes is unclear.

### **Pleural exudates**

The main causes are given in Table 43.2. Of these, the most common are metastatic tumour, infections and pulmonary embolism.

### **Neoplasms**

A primary pleural tumour is almost always a mesothelioma. Metastasis occurs commonly from bronchial, breast, stomach and ovarian carcinoma [29]. Almost any

other malignant neoplasm may occasionally metastasize to pleura, while lymphoma may cause effusion without necessarily causing pleural infiltration [30]. Malignant pleural effusions are usually, though not always, blood-stained and recur after aspiration.

**Infections**

Bacterial pneumonia is associated with pleural effusion in about 40% of cases [31]. Initially the effusion may be amber-coloured, containing predominantly polymorphs, but may progress to increasing turbidity with a high white cell count (empyema; see Chapter 14). Viral and mycoplasmal pneumonias rarely cause effusion, although tuberculosis remains an important cause. Recently, infection with hantavirus, an often fatal syndrome occurring particularly in North American Indians, has been shown to cause non-cardiogenic pulmonary oedema and pleural effusion [32].

The effusion associated with bacterial pneumonia is initially sterile. However, it may frequently be invaded by

the causative organism, leading to empyema or eventual healing by fibrosis. For this reason, aspiration to dryness (or as near as possible) is necessary at the time of presentation; it is unwise to wait in the hope of resolution of the effusion with antibiotic treatment of the original pneumonia.

Pleural effusion may occur as a complication of tuberculosis in four situations. In all cases the disease is due to actual infection of the pleura by tubercle bacilli, though tuberculin hypersensitivity probably plays a part in potentiating the reaction.

1 Effusion may occur as part of primary tuberculosis in children, when the peripheral focus or a caseating lymph node ruptures into the pleura [33]. This disease is now relatively uncommon in developed countries but typically presented between the age of 5 and puberty and occurred in about 7% of patients with primary tuberculosis [34]. The effusion usually occurs 3–6 months after infection, and is associated with general malaise, fever and pleuritic pain [35]. In the era before chemotherapy, it would usually resolve without treatment in 3–4 months, leaving only some blunting of the costophrenic angle and evidence of the primary complex. Nowadays this syndrome is seen more frequently in middle-aged and elderly subjects who may have lost their tuberculin sensitivity. At presentation they may have negative tuberculin tests though these invariably become positive within a few weeks [36].

2 Pleural effusion may present in adolescents or young adults, often after a few weeks of malaise, with acute pleuritic pain and fever. This presentation became much less common after the introduction of bacille Calmette–Guérin (BCG) inoculation in the UK, though it is not prevented by this altogether. The illness may initially manifest with recurrent dry pleurisy and all evidence of disease may disappear without treatment over a few months. However, up to two-thirds of these patients develop active pulmonary tuberculosis within the ensuing 5 years [37,38]. Moreover, a proportion of patients in whom treatment is started late or withheld because of diagnostic uncertainty progress to pleural fibrosis, which may cause serious restrictive impairment of lung function; these individuals ultimately require surgical pleurectomy. Early diagnosis and treatment is therefore important.

3 This type of tuberculous effusion, also now seen relatively rarely in the West, occurs when a tuberculous cavity in a patient with extensive postprimary disease ruptures into the pleura. This usually causes a tuberculous pyopneumothorax, the patient becoming breathless and complaining of pleuritic pain and increased malaise and fever (Fig. 43.4). Bronchopleural fistula may result and causes considerable management problems [39]. A fatal outcome is not infrequent in these circumstances. When resolution takes place, chronic fibrothorax is almost always the result, with extensive calcification [40] (Fig. 43.5). Before the modern era of antibiotics, this was also often the

**Fig. 43.4** Fatal left pyopneumothorax due to extensive pulmonary tuberculosis in an alcoholic woman.

**Fig. 43.5** Extensive right pleural calcification following tuberculosis effusion.

outcome of pleural effusion complicating artificial pneumothorax treatment for tuberculosis.

**4** Pleural effusion as a manifestation of disseminated tuberculosis in patients with AIDS is becoming increasingly common. These patients are usually very ill and deteriorate rapidly. The effusion may contain large numbers of bacilli, although the typical granulomatous histological changes are often absent [41].

The effusion in tuberculosis is rarely massive but often occupies about one-third to half the hemithorax [34]. The

fluid is usually serous and contains more than 50 g/L protein with a predominant lymphocytosis [35]. In immunocompetent people, the tuberculin test is almost always positive, save in the early stages when it may occasionally be negative; if so, it should be repeated 1 month later, when it has usually converted. The initial negativity may be due to the presence of circulating lymphocytes that suppress the activity of tuberculin-sensitized T lymphocytes [42]. Culture of pleural fluid is often negative, the chances of a positive result being increased in propor-

tion to the amount of fluid sent to the laboratory. However, pleural biopsies show granulomas in about two-thirds of patients; repeating the biopsies and culturing them may increase the rate of diagnosis to 90% [43].

Infection with the other pathogenic mycobacteria (*Mycobacterium kansasii* and *M. avium-intracellulare*) has been recognized more frequently as the incidence of tuberculosis has declined in the West, and these organisms are a well-recognized problem in the immunosuppressed. These conditions are discussed in Chapters 20 and 52. Pleural effusion occurs in about 5% of cases, usually in association with radiological evidence of intrapulmonary disease [44]. The clinical and radiographic features of the disease in the immunocompetent are usually indistinguishable from those of tuberculosis, the diagnosis being made bacteriologically from pleural fluid and biopsies.

Fungal infections of the lung are relatively uncommon in the UK, being seen mainly in immunosuppressed patients. However they are seen more often in the USA, where they are endemic in certain areas (see Chapter 21). Pleural effusion may occur in any pulmonary fungal infection and usually mimics tuberculosis clinically, radiographically and in the features of the pleural fluid. It may occur as a self-limiting process, together with fever and malaise, in the primary infection, or as a more intractable illness in association with rupture of a lung focus in post-primary or disseminated disease. It has been described in about 7% of patients with coccidioidomycosis [45], 10% of patients with blastomycosis [46] and rarely in histoplasmosis [47], cryptococcosis [48] and other fungal infections. It is an occasional complication of invasive or disseminated aspergillosis [49] and has been described very rarely in allergic aspergillosis [50].

*Actinomyces* and *Nocardia* sp., filamentous branching bacteria (see Chapter 21), may infect the lung and spread to the pleura. Either parapneumonic or infected effusions may occur, almost always in association with cavitating pneumonic changes in the ipsilateral lung [51–54].

Subphrenic infection, usually due to a perforated abdominal viscus, may spread up through the diaphragm. The effusion initially contains polymorphs but no organisms; untreated it progresses to empyema [55]. Diagnosis is aided by the presence radiologically of gas under the diaphragm [56]. The usual organisms are coliforms, streptococci and clostridia.

Hepatic amoebiasis may be complicated by serous pleural effusion, usually on the right side [57]. Hepatic abscess may rupture into the pleura causing empyema; occasionally a hepatobronchial fistula forms and the so-called 'anchovy sauce' sputum is expectorated (see Chapter 22). Hydatid disease, of either liver or lung, may also rupture into the pleura, in some instances causing an anaphylactic reaction, in others leading to hepatobronchial fistula [58,59].

### Immune disorders

Rheumatic fever, still quite uncommon in the West despite an apparent rise in incidence in the western USA, occurs frequently in the tropics and India, where it has an annual incidence of about 0.5 per 1000 among rural children [60]. It may be associated with pleurisy (usually accompanied by pericarditis). Pleural effusion apparently occurred in the past in about 10% of cases of acute rheumatic fever [61], although recent reviews do not mention this as a complication.

Rheumatoid arthritis may be accompanied by effusion in about 15% of males with the disease but only 2% of females. Typically the effusion occurs within about 5 years of the start of the disease, in patients with severe arthritis and subcutaneous nodules [62–64]. The effusion may be an incidental finding or may accompany worsening arthritis and increased systemic symptoms. The fluid is straw-coloured, often turbid and typically has a low glucose and pH and a high lactate dehydrogenase. Rheumatoid factor and immune complexes may be found in pleural fluid, often at higher titres than in blood [65,66]. Biopsies of pleura may show typical rheumatoid histology. Thoracoscopy shows a highly characteristic granular appearance to the parietal pleura, with some associated inflammatory changes on the visceral pleura [67]. The granular change is due to palisaded epithelioid cells and occasional giant cells, resembling an opened-out rheumatoid nodule. These nodules may be responsible for the production of the immune complexes often found in the fluid. The condition usually regresses gradually and eventually clears over several months. Corticosteroid treatment may be of value if started early but this has not been clearly established. Chronic persistence of the effusion or progressive pleural fibrosis may lead eventually to the need for pleurectomy. Occasionally the condition may be bilateral and associated with other pulmonary manifestations of rheumatoid disease. There also appears to be a risk of infection of these effusions, leading to empyema [68].

Systemic lupus erythematosus presents not infrequently with pleurisy and, in contrast to rheumatoid pleurisy, is more common in women than men [69–71]. The usual presentation is bilateral small effusions, though unilateral ones are not unusual. Some 40% of patients have pleural effusion at some stage [69,71]. Lupus cells may be demonstrated in the fluid as well as the blood and a high titre of antinuclear antibodies in the fluid is diagnostic [72]. The fluid is often blood-stained and tends to have a normal glucose and low lactate dehydrogenase. Effusions may of course occur in lupus secondary to other complications of the disease, such as uraemia or pneumonia, in which case these antibodies may be absent from the fluid. The lupoid effusion is unlikely to resolve spontaneously, but usually does so in response to corticosteroid treat-

ment. If this fails, cyclophosphamide or azathioprine may be necessary.

Other collagen diseases seem rarely to be associated with pleural effusion unless associated with lupoid features or as a complication of renal or cardiac failure or of pulmonary infection. Wegener's granulomatosis of the lung may be complicated by pleural effusion [73,74], though this is usually small and responds to treatment with cyclophosphamide.

The post-cardiac injury syndrome, a relatively uncommon complication of myocardial infarction or cardiac surgery, is characterized by malaise, fever and pleural and pericardial pain, usually coming on about 3 weeks after the cardiac injury. Effusions may occur in pericardium and pleura, and pulmonary infiltrates may be seen; the fluid is usually bloody with high glucose and pH, and difficulty is often experienced in differentiating the condition from pulmonary infarction. It usually responds to corticosteroid treatment.

### *Abdominal diseases*

Pleural effusion may occur as a complication of a number of non-infective abdominal conditions, apart from the infective ones mentioned above. Acute pancreatitis may lead to pleural exudate, probably by transmission of inflammation through the adjacent diaphragm and of fluid through diaphragmatic lymphatics [75]. The fluid is characterized by high amylase levels, often higher than in serum. Chronic pancreatitis may also cause pseudocyst formation, with a sinus developing between cyst and pleura [76]. Again the fluid shows high amylase levels. Pleural transudates may occur as a complication of ascites due to ovarian fibroma, Meigs' syndrome [27], but more commonly exudates are seen in relation to gastrointestinal or pelvic carcinomas. The late stages of renal failure may be accompanied by pleural and pericardial pain and effusions [77].

### *Pulmonary embolism and infarction*

This condition is described in Chapter 25. As stated above, massive embolism may lead to right-sided heart failure and pleural transudation, although two-thirds of effusions associated with infarction are exudates, sometimes blood-stained [22,23]. The fluid may contain a high proportion of eosinophils.

### *Other causes*

Pleural exudates are an unusual occurrence in patients with sarcoidosis, usually presenting when the disease involves the lungs and often other organs as well [78–81]. The effusions are usually small and contain lymphocytes predominantly [81]. The pleura contains sarcoid granulo-

mas that may be found on biopsy, sometimes leading to confusion with tuberculosis. Usually the tuberculin test is negative and the Kveim test or biopsy of other tissues confirms the diagnosis.

Occasional patients working with asbestos develop pleuritic pain and an effusion, which may be recurrent [82,83]. While this may be the first evidence of mesothelioma, it may be benign asbestos pleurisy. This condition is the most common asbestos-related disease during the first two decades of exposure at work, but may occur for the first time long after exposure has ceased. The effusion is sometimes blood-stained and shows no specific cytological features. It may be an incidental finding on chest radiography, and it is likely that this is the event that leads to diffuse pleural fibrotic changes in a proportion of asbestos workers (Fig. 43.6). The effusion is usually of small or moderate size and may be bilateral. It tends to recur after aspiration but eventually disappears, sometimes leading to pleural fibrosis [83,84].

The yellow nails syndrome is a condition of hypoplasia of lymphatic vessels, leading to lymphoedema of the limbs, dystrophic changes in the nails and, sometimes, intractable pleural effusions [85–87]. The nail changes, which are not always present, take the form of thickening, increased curvature in both long and transverse axes, transverse ridging and a yellow-brown pigmentation (Fig. 43.7). They also grow more slowly than normal. The condition usually presents in adult life and is distributed equally between the sexes. In some cases it appears to be inherited as a dominant characteristic [88]. The cause of the nail changes is not known but the lymphoedema and pleural effusions are related to lymphatic vessel hypoplasia, which may be demonstrated in the limbs by lymphangiography. The condition may be complicated by bronchiectasis, sinusitis or protein-losing enteropathy [89,90] and patients have an increased risk of neoplasms, especially lymphomas and sarcomas [87]. The effusions may not require treatment but can result in pleural fibrosis. If they are sufficiently large to cause symptoms, it may be necessary to carry out pleurodesis or pleuroperitoneal shunt [91]; occasionally pleurectomy has been carried out, and on one occasion the surgical specimen showed abnormal pleural lymphatic vessels [92]. It is assumed that this abnormality hinders the reabsorption of proteins in the fluid, thus leading to effusion [93]. Effusions may occasionally be chylous and have been managed by dietary reduction of fat intake [94].

Certain drugs may provoke pleural effusions as a side-effect (see also Chapter 55). Practolol and methysergide may have a direct effect on serous membranes, leading to effusion and fibrosis [95,96]. In addition, pleural effusion may be associated with eosinophilic reactions induced by such drugs as nitrofurantoin, sulphonamides, salicylates,  $\beta$ -blockers and para-aminosalicylic acid [97]. The eosinophilia-myalgia syndrome is associated with the use

of L-tryptophan [98]. As mentioned above, the lupus syndrome may be associated with pleural effusion and this may also be caused by drugs such as hydralazine, procainamide, phenytoin and isoniazid [99]. Effusion occasionally follows several months after a course of radiotherapy, though this is rarely large and usually resolves after aspiration [100]. It may also occur when pericardial effusion develops as a complication of mediastinal irradiation [101,102].

The syndrome of recurrent polyserositis, discussed previously, may cause effusions as well as pleural and peritoneal pain [10,11]. Finally, oesophageal rupture leads to mediastinitis with infection of the pleura and effusions containing a high level of salivary amylase, epithelial cells and often food particles [103–105]. It may be associated with mediastinal emphysema and usually follows oesophageal instrumentation, though spontaneous rupture does occur. It is important to recognize this condition early, as it is usually fatal if surgical repair and mediastinal drainage are not instituted promptly [106].

### Investigation

A pleural effusion is normally diagnosed by chest radiography, although loculated effusions may require confirmation by ultrasound. However, the radiograph does not usually provide diagnostic information on the cause of the effusion, although evidence of a proximal or pleural tumour or of tuberculosis may be seen. Similarly, the history and clinical examination may sometimes provide clues but do not often give a clear indication of the cause, except in the case of hydrothorax. When taking the history, special attention should be paid to previous illnesses, drug or radiation treatment and symptoms not directly related to the effusion. It should be apparent from the foregoing that pleural fluid often accumulates as a consequence of systemic disease.

If the history and examination indicate a clear cause, no further investigation is necessary though therapeutic aspiration may be desirable. Thus, evidence of congestive heart failure is sufficient to justify a trial of diuretic therapy prior to aspiration of a right-sided or bilateral effusion and evidence of venous thrombosis often leads to treatment with anticoagulants rather than aspiration. In most patients, however, pleural fluid needs to be aspirated.

### Pleural aspiration and biopsy

Pleural aspiration should normally be combined with pleural biopsy during the one procedure. The best method is to seat the patient on a stool leaning forward over the side of the bed, with arms folded under the chin. The site is chosen carefully, taking account of the likely position of the diaphragm and the top of the effusion as judged by

percussion. Simple M-mode ultrasound may be very helpful in aspirating loculated effusion [107,108]. Local anaesthetic is infiltrated intradermally, subcutaneously and into muscle and parietal pleura, infiltration continuing until fluid is aspirated. If the pleura is felt to be much thickened, a long lumbar puncture needle may be used. Careful attention to anaesthetic technique, together with a reassuring explanation of the procedure, makes the aspiration less of an ordeal for both patient and doctor.

Care should be taken to insert all needles immediately above the lower rib in order to avoid damage to intercostal nerve and vessels, which lie immediately below each rib. After finding the fluid it is sensible to take some specimens for chemistry, cytology and culture immediately, and to follow this by pleural biopsy. If tuberculosis is suspected, as much fluid as possible should be sent to the microbiology laboratory. Biopsy is usually carried out with an Abrams punch [109], which is inserted along the anaesthetic needle track after its enlargement with a fine-pointed scalpel blade. Biopsies should be taken first laterally and the punch should then be rotated inferiorly and through 180°, avoiding the region of the intercostal bundle. Four or five bites should be taken to increase the chances of a positive finding [110].

Having collected specimens for diagnosis, it may be desirable to remove fluid in order to relieve symptoms. This should be done by aspiration into a large syringe equipped with a three-way tap rather than by insertion of a tube, although tube drainage is often necessary if the fluid is infected. The syringe may be connected to a wide-bore needle (and, after biopsy, to the Abrams needle for convenience) or to a plastic cannula introduced through a needle; the latter method is more comfortable for the patient and involves less risk of puncturing the lung. Aspiration should take place relatively slowly (hence the disadvantage of a tube) since rapid removal of fluid may result in unilateral pulmonary oedema, a complication that may be fatal and which is probably due to increased microvascular permeability in the reinflated lung [111,112]. Removal of large amounts of fluid may also cause hypoxaemia, which can be alleviated by administration of oxygen [113]. It is probable that these complications are related to the generation of excessively negative intrapleural pressures and can be prevented by careful and slow aspiration [114]. If the patient complains of shortness of breath, pain in the chest or general unease during the procedure, it is wise to stop immediately and to take a chest radiograph to exclude pneumothorax or pulmonary oedema.

A fortunately rare complication, though seen occasionally, is air embolism when air is introduced into the pulmonary venous circulation. This may be immediately fatal or attended by loss of consciousness. The patient should immediately be laid down on the left side with head below feet; if a hyperbaric chamber is available its use may be

life-saving. Air embolism was a complication of the old artificial pneumothorax treatment of tuberculosis and thus was more familiar to an earlier generation of chest physicians. Pneumothorax is a more frequent complication of pleural aspiration, especially when done by the inexperienced. It is usually due to puncture of the lung, though a careless technique may allow introduction of air through needles or the chest incision. It may require tube drainage. Sometimes the introduction of a small amount of air is useful in a diagnostic sense, since it may demonstrate pleural tumour separate from the effusion. Other occasional complications attendant on careless technique include the introduction of infection and the inadvertent biopsy of lung, liver, spleen or even kidney.

### Examination of the fluid

#### *Macroscopic appearances*

The fluid of a transudate is clear and pale straw-coloured. Exudates tend to be more amber-coloured and may be turbid if the cell count is high. A fresh exudate often clots on standing, while an older one has often been defibrinated and, like a transudate, remains fluid. Blood in the fluid may be due to damage to a vessel during insertion of the needle or biopsy. If this is the case, the fluid withdrawn into the local anaesthetic syringe is usually clear and later aspirates tend to be less blood-stained than the initial ones. Uniform blood-staining, of a red or brown colour, frequently indicates pleural tumour, although infarction, rheumatoid, leukaemic and tuberculous effusions may be haemorrhagic. Milky fluid is usually due to chyle (see below), though chronic effusions can mimic this appearance due to the presence of fat globules derived from degenerating cells. Purulent fluid in cases of frank empyema is easily recognized, but lesser degrees of infection give the fluid an increased turbidity indistinguishable from that due to a high cell content. A fluid with a shimmering sheen may contain high levels of cholesterol [115], another indication that the effusion is chronic but of no further significance.

#### *Microscopic appearances*

A citrated specimen of the fluid should be examined for differential cell count and for malignant cells. The polymorph is predominant when there is an infective cause in lung or pleura, other than tuberculosis, while the lymphocyte is the characteristic cell in tuberculous effusions [116,117]. It is also frequently the predominant cell in malignant effusions. An eosinophilic effusion (with >10% of white cells being eosinophils) is a non-specific finding [118,119] that occurs in association with other diseases characterized by blood eosinophilia, such as pulmonary eosinophilia, polyarteritis nodosa, tropical eosinophilia,

filariasis and Hodgkin's disease, and also in the absence of blood eosinophilia when blood has been introduced into the serous cavity [120]. It is thus seen following trauma, pulmonary infarction and infection. It is relatively unusual in carcinomatous effusions [120]. Eosinophilic effusion has also been described in response to fungal and viral infections. It may be that the common factor is the escape into the pleural fluid of eosinophil chemotactic factor derived from white cells in blood.

The examination of pleural fluid for malignant cells may lead to the diagnosis. However, caution should be exercised in interpreting positive results, since desquamated mesothelial cells may easily be mistaken for malignant cells, even by experienced pathologists [20]. Nevertheless, a high diagnostic yield following careful cytological examination has been reported from specialized laboratories [121,122], and it is likely that the use of newer cell marker techniques will improve the reliability of these diagnostic tests.

#### *Bacteriological culture*

Culture of effusions should be carried out as a routine in order to guide therapy if infection is found. If tuberculosis is thought a possibility, several large specimens of fluid should be cultured, since the chances of a positive result increase with the amount of fluid examined.

#### *Biochemical tests*

It is usual to measure the protein content of pleural fluid, 30 g/L being taken as the dividing line between transudate and exudate [20,123]. In addition the pleural fluid-serum ratios of lactate dehydrogenase and cholesterol have been found useful in differentiation. Pleural fluid cholesterol is usually less than 55 mg/dL and the fluid-blood ratio is 0.3 or below in transudates [124]. The glucose level may be helpful because it is characteristically low (<1.7 mmol/L or 30 mg/dL) in rheumatoid disease. It may also be low in infected effusions or whenever there is a high cell count [125,126]. Lactate dehydrogenase is raised in exudates above the serum level, but otherwise is a non-specific finding [127]. Amylase levels may be very high (>1000 u/L) in effusions due to pancreatitis and oesophageal rupture [126,128]. The fluid pH is reduced (acid) in pleural inflammatory disease and has been used by some as guide to the use of tube drainage in empyema [129]. In general, however, biochemical tests are not very helpful in a diagnostic sense.

#### *Further diagnostic tests*

Ultrasound and CT are now standard investigations in most centres prior to biopsy and aspiration in order to detect evidence of malignant disease, either primary or

secondary [130,131]. These investigations are a particularly useful guide to the best site to biopsy, although it should be remembered that they cannot be relied on absolutely in the diagnosis of tumour and tissue diagnosis is necessary in most cases [132]. If clinical examination, aspiration and biopsy fail to give the diagnosis, further tests may be necessary. According to the surgeon's preference, thoracoscopy can be carried out using a rigid thoracoscope or video-assisted techniques with biopsy of any pleural lesions seen [133–135]. This has a high success rate in experienced hands. If it fails, a limited thoracotomy may be necessary for appropriate biopsies to be taken.

### Management

The management of pleural effusion depends on the cause. In many cases aspiration is sufficient to cure the problem, although some effusions do recur, especially malignant ones. Infective effusions should be treated with the appropriate antibiotics (see Chapter 14) and tube drainage may be necessary. Tuberculous effusions require antituberculosis chemotherapy along standard lines and it is usual to add corticosteroids (prednisolone 20 mg daily for 2–3 weeks, reducing over a further 2–4 weeks) as there is evidence that this speeds reabsorption and prevents pleural fibrosis [136,137]. Corticosteroids also speed the resolution of effusions due to sarcoidosis, systemic lupus erythematosus, the post-cardiac injury syndrome and possibly rheumatoid disease.

In general, recurrent exudates eventually heal themselves by causing pleural fibrosis; however, since this may cause serious restriction of lung movements the aim of treatment is to prevent it happening by early aspiration and appropriate drugs. However, if there is no specific treatment for the underlying disease and if the effusion is large enough to cause symptoms due to lung compression, treatment may be aimed at producing pleural obliteration by fibrosis. This is the case with malignant effusions, which rarely resolve spontaneously. Several methods have been used to promote pleurodesis, including instillation of nitrogen mustard [138], radioactive colloidal gold [139], tetracycline [140], doxorubicin [141] and quinacrine [142], all of which show a success rate of up to 60%. A suspension of killed *Corynebacterium parvum* has also been used and has been shown to be more effective than nitrogen mustard in controlled trials [143–145], causing less nausea than the former and producing pleurodesis in more than 90% of subjects. There is also some evidence that it lengthens survival in some of the patients [146]. The technique is to aspirate the pleural space until no more fluid is obtained and to inject 7 mg of heat-killed, freeze-dried *C. parvum* in 20 mL saline into the pleural cavity. The patient is then tilted in the bed and placed in series of different positions for 15 min each to ensure generalized distribution of the material over the pleural surface. The

usual side-effect is fever associated with malaise for 2–3 days. A brisk pleural reaction occurs that may cause widespread radiological shadowing before the space is obliterated. Reaspiration and a second instillation is sometimes necessary. The mechanism of action of *C. parvum* is not known, but it clearly excites a brisk fibrotic reaction and produces a thick rind round the lung. It may also have an indirect antitumour action, possibly by activating macrophages or natural killer cells [147].

Pleurodesis with *C. parvum* has been so successful in our hands that more aggressive treatment, with insufflation of kaolin or talc through a thoracoscope or intercostal tube or surgical pleurectomy, is now rarely necessary to prevent recurrent effusions. These techniques have been used widely, are effective [148–150] and there is still an occasional need for them, though thoracotomy should only be used as a last resort in patients with pleural tumour. In particular, when using talc for non-malignant effusions care should be taken to ensure that it is not contaminated with tremolite asbestos, the two minerals often occurring together in the same geological formations. Fortunately, one survey of patients many years after talc pleurodesis failed to show any case of mesothelioma developing to the time of the survey [151], and personal investigation of talc BP as used in the UK has shown no contamination.

## Chylothorax

### Anatomy and physiology

In general, the thoracic duct receives the lymph from both sides of the body below the diaphragm and from the left side above it. The lymph from the right side of the head and neck and right arm is drained into the right lymphatic duct, while that from the right hemithorax is drained into the right bronchomediastinal trunk. The thoracic duct begins in the abdomen as a dilatation called the cisterna chyli, which lies on the front of the upper two lumbar vertebrae between the aorta and the right crus of the diaphragm. The duct passes upwards through the aortic opening of the diaphragm, ascends in the posterior mediastinum behind the diaphragm and then the oesophagus, inclining to the left at the fifth thoracic vertebra to ascend in the superior mediastinum closely applied to the left side of the oesophagus. Entering the root of the neck, it turns laterally between the carotid sheath and the vertebral artery, then downwards in front of the subclavian artery and enters the venous system at the junction of the left internal jugular and subclavian veins. In rather fewer than 50% of subjects there are variations in the anatomy of the thoracic duct, two or more ducts frequently being present at some point in the course.

The right lymphatic duct is usually quite short, about 1 cm long, starting at the medial margin of the scalenus

anterior muscle above the subclavian artery where it is formed by the junction of right jugular and subclavian lymph trunks. The right bronchomediastinal trunk runs up the right side of the oesophagus into the neck. Both trunks end in the innominate vein, either separately or as a common trunk. Many anastomoses occur between the bronchomediastinal trunk, thoracic duct and the azygos, intercostal and lumbar veins, so that the thoracic duct may be ligated at any point in its thoracic course without causing problems of lymph drainage [152,153]. This is important in the management of chylothorax.

The chyle that drains up the thoracic duct is an alkaline fluid which may be milky or almost serous in appearance depending on the nutritional state of the subject. On standing it separates into a creamy upper layer rich in chylomicrons, a milky middle layer and a lower layer containing lymphocytes. It has a protein content of 20–60 g/L and a fat content of up to 60 g/L. The amount of chyle produced daily may be as much as 2.5 L [154], again depending on the subject's nutritional status and especially the fat content of the food. Thus the rate of accumulation of a chylothorax may be controlled by dietary measures [94].

### Clinical features and aetiology

There are no specific clinical features associated with chylothorax, which presents as does any other pleural effusion. It may be bilateral or unilateral, with a tendency to be right-sided with lesions of the thoracic duct below the fifth dorsal vertebra and left-sided with lesions above that level [155]. It is usually not associated with pleural pain, and infection does not occur because of the antibacterial properties of chyle. The diagnosis is made on aspiration of the fluid, although this is not always obviously milky; it may require biochemical analysis of triglycerides and chylomicrons to confirm the diagnosis [156]. Alternatively, detection of dye or radioactivity in pleural fluid after the patient has eaten butter containing a lipophilic dye or radioiodine-labelled triglyceride also allows confirmation [155,157].

If the effusion is milky, the only possible cause of confusion is the so-called chyliform, pseudochylous or cholesterol effusion [158]. This is usually readily distinguished because it is due to fat globules from degenerating cells in long-standing encysted effusions, usually secondary to tuberculosis or rheumatoid disease. The history and features of the primary condition should allow the distinction to be made without difficulty; if not, the presence of cholesterol crystals and negative dye or radioiodine tests settle the matter.

Chylothorax is uncommon. The most frequent cause is tumour [159], especially lymphoma and metastases from stomach and gastric carcinoma to mediastinal nodes. Occasionally radiotherapy to these tumours may provoke

the chylothorax. Extensive blockage or invasion of the duct, with fistula formation, or invasion of the left subclavian vein is responsible. Some 50% of cases are due to tumour, while about 25% are due to trauma [159]. Half of these are the result of damage to the duct at surgery [160,161], especially in the region of the left subclavian vein, though many cervical and thoracic operations may cause this, from neck dissection, cervical sympathectomy and oesophagectomy to coronary bypass, high lumbar aortography and diaphragmatic hernia repair. The other half are due to knife and bullet wounds or stretching and bending injuries to the spine; sometimes these may be surprisingly minor, such as coughing, straining or vomiting [162,163]. Of the remaining 25% a few may be due to tuberculous mediastinal nodes, filariasis, left subclavian vein thrombosis, thoracic aortic aneurysm, lymphangioma and thoracic duct lymphangioma, sometimes associated with generalized lymphangioma and lymphoedema [164,165]. Finally, a proportion of cases seem to have no obvious cause. This is particularly so with the neonatal type [166], which presents within a day or two of birth and, though rare, is the most common cause of pleural effusion at that early stage of life.

Traumatic chylothorax usually presents 2–10 days after the injury, the interval being the time taken for a mediastinal chylous cyst to rupture into the pleura [167]. Drainage is only required to relieve the symptom of increasing dyspnoea; however, since recurrent aspirations are almost always necessary, this leads to the important complication of nutritional deficiency. Thus emaciation and dehydration occur quickly without appropriate treatment, death ensuing.

### Management

If the patient's nutritional status can be maintained, spontaneous or traumatic damage to the thoracic duct may heal. Thus, in such cases, a trial of conservative treatment is justified [168]. This means tube drainage of the pleural space, reduction of chyle formation by cessation of oral feeding and total parenteral nutrition. Assuming the patient's nutritional status is maintained, it is reasonable to wait about a week to see if the drainage of chyle is ceasing. If it is not, surgical treatment is indicated [169]. The surgeon usually attempts to locate the tear, using an injection of Evans blue dye into a leg as a marker, and suture the duct above and below it [155]. Alternatively, active attempts at talc, kaolin or tetracycline pleurodesis, combined with tube drainage, may be used at an early stage and have been reported to be successful [170,171].

In the case of non-traumatic chylothorax, the treatment is planned in the light of the primary disease, bearing in mind the principles of maintaining nutrition and preventing chyle leaking into the pleura. Thus, lymphoma may

well respond to radiotherapy or chemotherapy, although pleurodesis and tube drainage as above may be necessary as well. Symptomatic relief in the case of metastatic carcinoma may also be provided by radiotherapy, though pleurodesis or low thoracic duct ligation may also be necessary. In some cases of terminal disease, it may be kinder to avoid all such measures and simply palliate the patient's symptoms with appropriate drugs.

## Pleural plaques

### Clinical features

Pleural plaques are benign fibrous lesions of the parietal pleura that occur as a result of exposure to asbestos; however, they may frequently be found at postmortem in people in whom such exposure was not known. Radiologically they present as indistinct elevations of the pleura [172], which may easily be missed unless they are large

and multiple (Fig. 43.8); indeed one autopsy series has shown only a 15% ante-mortem diagnosis rate [173]. Moreover, pleural fat pads and companion shadows may easily be mistaken for plaques, leading to a tendency to false-positive diagnoses. Thus diagnosis of fibrous plaques by routine chest radiography is unreliable. However, most long-standing plaques calcify and this leads to characteristic radiological shadows, often seen most distinctly as elongated 2–3 mm wide calcifications on the lateral chest wall, diaphragm and pericardium but also *en face* as 'holly leaf' shadows (Fig. 43.9). In cases of doubt, and where the additional radiation is considered justified, CT proves a reliable means of diagnosing and defining the extent of plaques [174]. Parietal pleural plaques would not be expected to cause any detectable lung functional impairment; studies demonstrating abnormalities in such subjects are likely due to the effects of asbestos exposure or some confounder, usually cigarette smoking, on the lungs.

### Pathological features

Pathologically, pleural plaques are smooth, whitish-

**Fig. 43.8** Fibrous pleural plaques (arrowed) in retired asbestos worker, best seen in left mid zone and under lateral chest wall.

**Fig. 43.9** Calcified plaques on diaphragm and, *en face*, in right mid zone (arrowed).

**Fig. 43.10** Diaphragmatic pleural plaques as seen at necropsy.

yellow elevations of the parietal pleura, separated distinctly from surrounding mesothelium and having their centres usually over a rib or over the central tendon of the diaphragm (Fig. 43.10). They vary in size from pin-head to

that of a hand and are almost always multiple. Histologically, they consist of collagen arranged in a basket-weave pattern and covered by an intact and non-metaplastic mesothelial layer [175]. In their deeper layers there may be

small collections of lymphocytes and plasma cells. Asbestos fibres may be found in plaques by electron microscopy but are usually too small and sparse to be seen by light microscopy. Electron microscopy has shown these to be predominantly short chrysotile fibres [176]. Asbestos bodies are not present in plaques, although they may be found in the subject's lung.

### Aetiology

It is well established that plaques occur most frequently in populations exposed industrially to asbestos, although exposure does not have to be heavy or prolonged [177]. Usually plaques only make their radiological appearance about 10 years, and calcification usually only 20 years, or more after first exposure. They have also been found in populations exposed to the non-asbestos fibrous mineral erionite present in the environment in certain parts of Turkey [178,179], and in people exposed environmentally, rather than occupationally, to naturally occurring soil or rock asbestos in parts of Finland, central Europe, Turkey and Greece [180,181].

It is likely that pleural plaques are a benign reaction to an individual fibre or a very small number of fibres that have lodged in the parietal pleura, probably being transferred via pleural lymphatics. Their site, centred over ribs and diaphragmatic tendon, suggests that the fibre's progress through the lung, as a result of forces exerted by lung movement, has been arrested by impenetrable tissue. There is no evidence that the plaque is in any way premalignant, although a subject with plaques has been exposed to asbestos and may be at increased risk of lung cancer or mesothelioma in relation to the intensity and duration of such exposure.

### Management

Pleural plaques are of no account save as a marker of asbestos exposure. Since they are benign, reassurance should be given to the individual in whom they are found and he or she should not be followed up in clinic. The risk of mesothelioma in such an individual is likely to be greater than in someone without plaques, and depends upon their exposure to asbestos rather than the presence of the plaques (see Chapter 54). In any case, the risk cannot be reduced further by any action other than by ensuring no future exposure to asbestos. However, a number of people with plaques and no other disease have received compensation for having these wholly benign lesions, thus increasing anxiety and public misconceptions about their nature. The sensible physician recognizes and attempts to allay the natural anxiety of a patient in whom these plaques have been found, and is now able to provide a sensible risk estimate based on likely past exposure to asbestos (see Chapter 54).

### Pleural fibrosis

Distinction should be made between pleural plaques, which are well-demarcated lesions of the parietal pleura, and pleural fibrosis, which is a diffuse process involving both layers of pleura and not infrequently extending into the surface of the lung.

### Clinical features

Pleural fibrosis is usually the sequel of an unabsorbed pleural effusion, although the presence of the effusion may not have been recognized clinically (see Fig. 43.6). Thus it may present in a patient with a recent history of effusion or episode of pleural pain, or it may be found incidentally on chest radiographs. The lesion may be unilateral or bilateral. Whether it is associated with symptoms depends on its extent and on the health of the underlying lung; in general, bilateral thickening has to be quite extensive before it interferes seriously with lung expansion, while unilateral thickening is unlikely to cause symptoms unless associated with other lung disease. The physiological effects of pleural fibrosis are decreased lung volumes, without reduction in transfer coefficient, and decreased compliance. These features may be associated with exertional dyspnoea. Chest pain is not usually a feature and when it is present it should always lead the physician to suspect that the pleural thickening is due to tumour rather than fibrosis. However, it is apparent that some patients with asbestos pleural fibrosis present to their doctors with pleuritic pain or with a persistent chest wall ache [182].

The radiological features vary according to the cause. There may be localized lower zone thickening with obliteration of the costophrenic angle following an unresolved effusion, or more generalized changes. These may have the appearance of 'crow's feet', irregular streaky shadows, diffuse thickening of pleura or a combination. Calcification may be present; if this is unilateral the fibrosis is likely to be due to an old haemothorax or tuberculous effusion, but if bilateral is almost certainly due to asbestos exposure (Fig. 43.11). Grossly thickened pleura with nodular changes is unlikely to be due to fibrosis alone and usually indicates pleural infiltration by carcinoma or mesothelioma.

Occasionally, pleural thickening is responsible for distortion and atelectasis of underlying lung with infolding of pleura, causing appearances resembling tumour. This appearance is sometimes called Blesovsky's syndrome [183,184]. It should be noted that it occurs with diffuse thickening and not with pleural plaques. Some patients with this syndrome may complain of persistent non-pleuritic chest pain.

The clinical course of pleural thickening is varied. In many cases it does not progress. However, when the cause

**Fig. 43.11** Extensive bilateral calcified pleural fibrosis in pipe lagger exposed for many years to asbestos.

is still active, as for example with collagen disease, asbestos and drug therapy, it may progress, infiltrate the peripheral lung and cause restrictive interference with lung function. Pleural thickening is often associated with physical signs. The localized type mimics pleural effusion, with local reduction in movements, percussion note and breath sounds. The generalized type may cause marked limitation of chest wall movements, retraction of intercostal spaces and flattening of the chest wall, mimicking the features of extensive pulmonary fibrosis. As stated above, in such cases lung fibrosis is often present also by extension from the pleura. It is not uncommon to be able to hear inspiratory crackles and there is evidence that these may in some cases originate in the pleura and be distinct from those due to underlying pulmonary fibrosis; in such cases there may be a mid-expiratory component [185].

**Causes**

Any cause of pleural exudate may be responsible for the subsequent development of pleural fibrosis, usually of the localized type. However there are relatively few commonly recognized causes of general pleural fibrosis (Table 43.3). If it is calcified, it is likely to be due to old empyema or haemothorax, tuberculous effusion, artificial pneumothorax treatment or asbestos exposure [186]. Bilateral, diffuse, non-calcified thickening suggests a collagen disease or therapy with  $\beta$ -blockers or methysergide [95,96] (Fig. 43.12).

**Table 43.3** Causes of generalized pleural fibrosis.

Tuberculous effusion	Unilateral	Calcified
Old artificial pneumothorax	Unilateral	Calcified
Haemothorax	Unilateral	Calcified
Multiple rib fractures	Either	Either
Old empyema	Unilateral	Either
Thoracotomy, thoracoplasty	Unilateral	Uncalcified
Radiation therapy	Unilateral	Uncalcified
Rheumatoid disease	Bilateral	Uncalcified
Systemic lupus	Bilateral	Uncalcified
Drugs (practolol, methysergide)	Bilateral	Uncalcified
Asbestos exposure	Usually bilateral	Calcified
Silicotic massive fibrosis	Overlying the PMF	Uncalcified

PMF, progressive massive fibrosis.

**Investigation and management**

The clinical history and chest radiograph are usually sufficient to lead to the diagnosis. Care should be taken to exclude asbestos exposure and drug therapy as causes. In the case of the former, diffuse pleural thickening should only be attributed to asbestos exposure if the patient has worked regularly with the material; occasional, incidental or non-occupational exposure to asbestos is very unlikely to cause anything other than pleural plaques. There is evidence from lung asbestos counts that diffuse pleural fibrosis occurs at exposure levels comparable to those that cause early asbestosis [187].

**Fig. 43.12** Bilateral non-calcified pleural fibrosis in patient treated for 10 years with methysergide for migraine.

**Fig. 43.13** High-resolution CT scan of asbestos worker showing diffuse pleural fibrosis with some extension into underlying lung. Calcification is visible bilaterally.

The main problem in diagnosis is differentiation of the lesion from malignant infiltration of the pleura, especially by mesothelioma. Mesothelioma is usually unilateral and associated with some nodular change. However, metastases and alveolar cell carcinoma may present with bilateral pleural involvement. If a primary tumour is not demonstrable, bronchoscopy and needle biopsy of the

pleura may be necessary, though these investigations may be avoided if the appearances are shown to have been present on previous radiographs. CT may be useful in deciding whether extension of the fibrosis into lung has occurred and when surgical treatment is being contemplated [188], and is commonly used in the assessment of asbestos disease (Fig. 43.13).

Apart from the treatment of any underlying cause, such as cessation of drugs or appropriate therapy for collagen disease, there is only one therapeutic decision: whether to seek the advice of a thoracic surgeon. Pleurectomy and 'decortication', i.e. removal of the thick fibrous peel, may release the lung and chest wall and thereby relieve the restriction to ventilation. This operation has much to offer in the case of localized fibrothorax following empyema or tuberculous effusion and surgical advice should be sought early in these situations [189]. Where fibrosis is generalized and well established, the decision should be made after consideration of the patient's disability and age and in the knowledge that the procedure may be hazardous and not produce a dramatic improvement. In particular, care should be taken to assess the underlying lung for the presence of disease such as fibrosis and bronchiectasis and for the extension of pleural disease into its surface; the former prevents a good functional result while the latter causes surgical difficulties and complications. Bronchoscopy, bronchography, CT and regional lung function testing may all be of value in coming to a decision about surgery. In general, the more recent the development of the fibrothorax, the more likely is surgical success, and the more extensive the fibrosis, the better the functional result after surgery. Patients with Blesovsky's syndrome not infrequently undergo surgery in the belief that the lesion is a tumour. Long-term results are generally satisfactory in that it does not recur, although lung function may not improve and may even deteriorate [190]. Operation for asbestos pleural fibrosis is inadvisable since the underlying lung is usually involved and results are likely to be poor.

## Tumours of the pleura

Secondary tumour of the pleura is quite common and is discussed briefly in Chapter 42. Primary pleural tumour is increasing in incidence. The most important and most common, occurring in over 1000 people annually in the UK, is malignant mesothelioma. Benign mesothelioma or fibroma and sarcoma are very uncommon primary pleural tumours.

### Localized fibrous pleural tumour (pleural fibroma, benign mesothelioma)

#### Clinical features

This tumour [191–193] may present as an incidental radiological finding or on account of symptoms; when these are present they may be due to direct pressure effects of the lesion, which cause breathlessness, or to one of the recognized indirect effects: fever and chills [194,195], hypoglycaemia [196] or hypertrophic pulmonary osteoarthropathy [197]. The patient is usually over 40,

although children have been described with the disease. Clinical signs depend on the size of the tumour, which may be very large and mimic massive pleural effusion; in one case, signs suggestive of constrictive pericarditis related to gross mediastinal displacement have been reported [195].

The radiological appearance is usually that of a spherical or lobulated peripheral mass adjacent to the pleura. Occasionally it may have a broad base (Fig. 43.14a) but more usually the pleural connection is a narrow pedicle. As it may arise from parietal or visceral pleura, it may occur anywhere on the chest film in relation to chest wall, diaphragm, mediastinum or fissures. In fissures it may have an ovoid shape. It may be complicated by pleural effusion, which is sometimes blood-stained [194,198].

Pathologically, the tumour is well encapsulated, surrounded by compressed lung, from which it can be shelled out easily. The histological appearances are predominantly of interlaced fibrous tissue with few mitotic figures and areas of myxomatous degeneration (Fig. 43.14b). However, pleomorphic types are well recognized and there may be difficulty in deciding whether the tumour has undergone sarcomatous change [191,199]. While the cell of origin may be mesothelial in some cases, in others the histology suggests submesothelial mesenchymal origin [191].

#### Investigation and management

Localized fibrous tumour can rarely be distinguished clinically from bronchial carcinoma; in any case, because of its potential for malignant change the treatment is surgical. Sometimes the presence of hypertrophic osteoarthropathy in association with a tumour adjacent to the pleura suggests the diagnosis. The presence of a haemorrhagic effusion should not prevent surgery.

Surgical resection can usually be carried out without removing lung and is normally curative. Secondary effects of the tumour, such as fever and joint pains, disappear by the time the patient wakes from the anaesthetic, while the clubbing and swelling of the osteoarthropathy settle over a month or two. The tumour may sometimes recur and need further resection; osteoarthropathy may be the symptom that announces this. Occasionally the tumour behaves like a sarcoma and metastasizes widely.

#### Pleural sarcoma

This is a very rare and highly malignant tumour that occurs predominantly in young adults [191]. Although it may be confused histologically and radiologically with fibrous or malignant mesothelioma, it is distinguished by the age group of the patient and the tendency to metastasize early. The clinical course is characterized by local invasion of lung and chest wall as well as by blood-

(a)

(b)

**Fig. 43.14** (a) Broad-based chest wall tumour in left upper zone. At operation this proved to be a fibroma. (b) Histology of resected specimen showing admixture of spindle cells and mature collagen.

borne metastases. Histologically it has a pleomorphic appearance, with spindle and polygonal cells with many mitoses.

### **Malignant mesothelioma**

#### **Aetiology**

Before 1960, malignant mesothelioma [200] was regarded as a very rare tumour of unknown aetiology. Several classical cases were described from Glasgow in 1945 but their histological classification was not recognized [201]. In

1960, however, Wagner and colleagues [202] described a large cluster of patients with the disease in the crocidolite asbestos mining area of the North-Western Cape in South Africa. Many further studies have now confirmed the strong association between the tumour and exposure to crocidolite, especially in asbestos product manufacture, ship-breaking and gas mask production. There has been much debate about two other important matters with respect to aetiology: whether all types of asbestos cause the disease, and how large an exposure is necessary for the risk of mesothelioma to be incurred. With respect to the former, animal studies have shown that any asbestos type,

indeed many synthetic and other naturally occurring fibrous minerals, provoke mesothelioma when injected directly into the pleural or peritoneal cavity, although the frequency of this response differs with dose and with different mineral types [203]. However, studies of human populations have shown that the risks of mesothelioma are remote in people exposed only to chrysotile [204], definite in those exposed to amosite [205] and high (up to 10% after as little as a year's exposure) in those exposed to crocidolite [206]. These exposures apply to an occupational setting; para-occupational exposures, such as regular washing of a worker's overalls or close proximity to asbestos insulation work, may also involve high and prolonged dosage and may lead to mesothelioma [207]. The second, and connected, question concerns the amount of asbestos required to provoke mesothelioma. Evidence from pure exposures to crocidolite and amosite has shown that the disease may develop after exposures (almost certainly to very high fibre levels) for as little as 6 months [205,206]. However, there is no evidence associating the disease with exposures to the very low levels that may be found in buildings with undisturbed asbestos walling or insulation. Non-occupational exposures leading to mesothelioma have been described, for example children habitually playing on asbestos waste tips or people living close to a heavily polluting asbestos factory, but these levels of exposure have almost certainly been of the same order of magnitude as those of asbestos workers [207].

The apparent conflicts between the human and experimental data on aetiology are resolved by the hypothesis that chrysotile, while carcinogenic to the pleura, does not normally reach the target organ in sufficiently large doses to initiate the process. Two factors may be responsible for this: (i) its curly nature prevents sufficient being inhaled and (iii) once inhaled the fibres do not reach the pleura in sufficient numbers. Support for the hypothesis comes from the observation that in people with mixed exposures to asbestos much less chrysotile is found in the lungs at postmortem than would be expected from the exposure history, while proportionally much larger amounts of crocidolite or amosite are found [208]. It seems likely that chrysotile does not penetrate so readily into the lung because of its physical and mineralogical characteristics; once in the lung, over the years of residence it is gradually broken down into microfibrils sufficiently small to be removed by macrophages.

Thus it can be stated with reasonable confidence that mesothelioma is a disease that occurs in people who have been exposed to relatively high levels of crocidolite or amosite in the past, almost always as part of their occupation. In people with no known exposure to these minerals, the risk is about one in a million, since sporadic cases unassociated with any known aetiological agent do occur; in those with heavy past exposure, the risk may be as high as 15%. However, in terms of predicting risk in the

majority of patients presenting with fear of future disease, these figures are often unhelpful since people have usually had mixed exposures in the user industries and never know exactly what they have worked with. The matter of predicting risk is discussed in the section on management.

Mesothelioma has also been described in people living in parts of rural Turkey. Two endemic areas have been discovered, one where the use of naturally occurring tremolite asbestos as building material and whitewash is responsible [180] and another where a non-asbestos mineral, fibrous erionite, is thought to be the cause [178]. The importance of the latter observation is that erionite, though fibrous, is not related to asbestos, thus lending strong support to the hypothesis that the propensity of a mineral to cause mesothelioma is due to its physical rather than its chemical properties. This casts doubt over the safety of a number of other fibrous substitutes for asbestos, such as artificial glass and carbon fibres and naturally occurring vermiculite and wollastonite. So far no epidemiological or clinical evidence has implicated these substances in the causation of mesothelioma, although superfine glass fibres have caused the disease when injected directly into the peritoneum or pleura of rats [209]. It would therefore be prudent for industry to avoid the use of such very fine fibres and to confine commercial interest to those outside the respirable range.

One other intriguing clue to the aetiology of mesothelioma has come from a study that has shown DNA sequences resembling those of a monkey virus, SV40, in human mesothelioma tissue. This virus contaminated some of the injected Salk poliomyelitis vaccines used in the 1950s and, if these observations are confirmed, may be a factor predisposing some individuals to the disease, perhaps acting in synergy with asbestos [210,211].

Approximately 1000 people each year die of mesothelioma in the UK, this figure having risen annually since reliable records were first kept in the late 1960s. This rise has been related to the much increased importation of all forms of asbestos during and after the Second World War that continued almost exponentially until 1970. In that year, crocidolite was effectively banned and control of the use of all asbestos considerably tightened. By 1980, importation of amosite had ceased and that of chrysotile had reduced substantially (Fig. 43.15). Unfortunately, this continued extensive use of asbestos for at least 20 years after the association with mesothelioma was described, together with the fact that once in place the mineral remains a threat to those who are required to remove or otherwise work with it, means that the epidemic of mesothelioma is likely to continue rising for a further 20 years and ultimately may be responsible for some 3000 deaths in the UK each year [212]. Mesothelioma is now the most common of the serious dust-related diseases seen in the UK, as well as being the most fatal.

**Fig. 43.15** Importation of asbestos into the UK and predicted annual deaths of British men from mesothelioma. (From Peto *et al.* [212] with permission.)

### Clinical features

Mesothelioma may affect pleura, peritoneum or pericardium [213]. The last two sites are much less common than the first, and peritoneal mesothelioma seems to have occurred more frequently in the past, reflecting particularly high previous exposures. The tumour characteristically presents 20–40 years after first exposure to asbestos, and often the victim has forgotten that he or she worked with the mineral. However, it is usually possible to obtain a history of work likely to have entailed exposure; jobs in railway workshops, shipyards, ships' engine rooms, gas mask or asbestos manufacture, thermal insulation or building are those most frequently associated with the disease. The first symptoms of mesothelioma are those associated with pleural effusion, breathlessness and chest pain. Often the chest pain is a persistent dull ache, but it may be severe. As the disease progresses, the pain and breathlessness become more troublesome and the patient loses weight. Distant metastases rarely present clinical problems, although they are usually found at post-mortem. Local spread of disease, causing cardiac tamponade, superior caval or oesophageal obstruction, spinal cord and intercostal nerve involvement or chest wall infiltration, is a usual feature; tumour very frequently grows through thoracotomy scars and not uncommonly through needle tracks. Examination of the patient reveals the signs of pleural effusion, though mediastinal displacement to the opposite side is unusual; this combination of appar-

ently massive effusion without displacement of the heart should lead to suspicion of malignant pleural disease. Finger clubbing and hypertrophic osteoarthropathy are rare.

The radiographic features are usually of a large pleural effusion. If the pleura can be seen, pleural nodules may be visible (Fig. 43.16). The lesion is almost always unilateral, although spread across the mediastinum sometimes occurs. Other features of asbestos-related disease may be seen, such as pleural plaques or asbestosis in the opposite lung.

The diagnosis is made on the history and by needle biopsy of the pleura. Typically an attempt to aspirate the effusion is thwarted by encountering much-thickened pleura, and biopsy of this with a cutting needle or drill may show characteristic features. If fluid is withdrawn, it is an exudate and often haemorrhagic. Hyaluronic acid may be present in the fluid or tissue, and cytology with electron microscopy may be useful in the hands of experts [214,215]. However, often the diagnosis cannot be made on examination of the fluid. Moreover, needle biopsy specimens may provide insufficient tissue for a firm diagnosis to be made. In these circumstances, it is wise neither to repeat the procedure too frequently nor to resort to thoracotomy for diagnosis; evidence of pleural tumour, consistent with the diagnosis, is sufficient to exclude a treatable cause of the pleural disease and is also adequate evidence in the UK for industrial injuries benefit to be paid.

The only treatable condition that may mimic mesothelioma is tuberculous pleural disease, and diagnostic efforts should be directed towards excluding this. However, the usual problem in differential diagnosis is whether the condition is mesothelioma or secondary pleural carcinoma. The latter is usually bilateral, except when due to bronchial or breast carcinoma. Certain tumour markers may be helpful in differentiation if the histological appearances are equivocal. Secondary adenocarcinomas frequently stain positively for carcinoembryonic antigen or  $\beta_1$  pregnancy-specific glycoprotein, whereas mesothelioma is usually negative for these [216]. However, until satisfactory treatment becomes available for these tumours, differentiation is of no value to the patient.

The clinical course of mesothelioma is one of steady deterioration to death over 1–2 years; patients are only rarely alive more than 2 years after diagnosis, although there is some evidence that those with a predominantly epithelial histological pattern have a somewhat better prognosis, a few long-term survivals in this group having been described [200]. Death usually occurs after a prolonged period of increasing chest pain and breathlessness, and may be precipitated by terminal infection or cardiac involvement. Loss of appetite and weight are constant features.

**Fig. 43.16** Unusual presentation of mesothelioma without pleural effusion but with extensive tumour in left upper chest wall.

### Pathology

The gross appearances are of a thick rind of white or grey-yellow tissue surrounding the lung and usually involving both pleural layers [217,218] (Fig. 43.17). The pleural space may be wholly or partly obliterated; where it persists it contains mucinous or haemorrhagic fluid. The tumour infiltrates lung, chest wall and diaphragm, and is frequently present in surgical wounds and needle tracks. Although few in number, metastases are frequently present in lung, nodes and other viscera.

The histological appearances vary, reflecting the potential of mesothelial cells to differentiate into epithelial or mesenchymal tissue. Typically there is much collagen, often containing clefts lined by tumour cells (Fig. 43.18). The predominant histological pattern may be epithelial, consisting of cuboidal or flattened cells forming tubular and papillary structures separated by a matrix that may consist of closely packed spheroidal cells, collagen or a mixture. This type may be confused with adenocarcinoma, especially with small biopsies, and it is in these circumstances that special stains may be of value in differentiation. The other main histological type consists of diffuse spindle cells, resembling sarcoma. Frequently the two types coexist in different areas of the same tumour. There is some evidence that the epithelial type has a

slightly better prognosis than the mixed and sarcomatous types. Asbestos bodies are not usually seen in the tumour but may be found in the lungs of the patient. Analysis of lung tissue using phase-contrast optical microscopy for uncoated asbestos fibres usually reveals large numbers [219]. Electron microscopy is necessary to analyse the fibres, since it is not possible to differentiate asbestos from other fibres commonly found in lungs by light microscopy [220]. Electron microprobe analysis usually shows the asbestos present to be predominantly crocidolite or amosite, since over time chrysotile dissolves. It should be stressed that such expensive and time-consuming analyses are of great value in research into asbestos-related diseases but have no useful application in clinical diagnosis. However, they are used increasingly in litigation issues, since the very large numbers generated by these methods have an impressive effect on judges and juries.

### Management

The prospects for curative treatment are not good. Surgery, radical radiotherapy and chemotherapy have all been tried and a number of enthusiastic reports published. However, none of these has been controlled and the few long-term survivors are matched by those from untreated

series. In particular, it is wise to be sceptical of reports of improved survival rates in people treated for 'early disease'. Clearly, the earlier intervention occurs in the natural history of a disease, the longer the apparent sur-

**Fig. 43.17** Excised lung with surrounding mesothelioma. Some metastatic deposits are also visible in the lung.

vival unless the treatment actually reduces it, and it is therefore necessary in any such research to have controls in order to demonstrate benefit convincingly. Surgery, which is popular in the USA, has a high mortality and is attended by considerable discomfort. Radiotherapy may produce some regression and prevent reaccumulation of fluid, although the author's experience suggests that it has a useful place in palliation of tumour growing through aspiration tracks or wounds and might also have a prophylactic role after aspiration or pleural biopsy. Single-agent therapy with doxorubicin, cyclophosphamide, interferon  $\gamma$  and other drugs and multiple regimens have been tried, all with anecdotal reports of improvement. Perhaps the most promising has been interferon  $\gamma$  administered intrapleurally, although in this study the response was seen only in very early cases who might well have been expected to live longer anyway [221]. There is clearly a need for multicentre controlled trials, and until then the management of individual patients must depend on the physician's judgement. Since the chances of achieving long-term remission seem as bad with treatment as without and the side-effects of treatment often add to the patient's misery, it is wise to confine treatment to palliation of symptoms with appropriate analgesics. Radiotherapy or *C. parvum* pleurodesis may be helpful in preventing recurrent effusions and the former may be useful in the relief of local bone or nerve pain or in reducing the size of subcutaneous extensions of tumour.

An increasingly frequent aspect of management related to mesothelioma is the requirement to advise patients who have been exposed to asbestos about their risks of developing the disease. This arises particularly in relation to the finding of pleural plaques on a chest radiograph, which sometimes leads to ill-considered advice to sue an employer rather than to reassurance

**Fig. 43.18** Histological appearance of a malignant mesothelioma showing tubopapillary tumour to the left and sarcomatous cells to the right. Note the mitotic figure in the mid right (haematoxylin & eosin  $\times 300$ ).

about the benign nature of this condition. It is now possible to make reasonable predictions of risk from the epidemiological study of Peto and colleagues [212]. These authors have calculated lifetime probabilities of death from mesothelioma for British males by year of birth. For those born between 1933 and 1938 the risk is about 8 per 1000, rising to about 12 per 1000 in the 1943–48 birth cohort. These estimates may be multiplied by the relative risks for different trades (e.g. 7 for metal plate and shipyard workers, 4 for plumbers and 3 for electricians) to give an estimate that can be further weighted by a detailed knowledge of the individual's exposure history within the confidence intervals given in the paper. Thus a shipyard worker, such as a shipwright or boilermaker, born in 1943 might have a lifetime risk (assuming typical exposure to asbestos in that trade) of about 8%. This can be explained

to an individual in relation to risks of other diseases such as heart attack or any type of cancer in order to put matters into some sort of perspective. It has to be said that this form of prediction has become a necessary part of the business of preparing a medicolegal report and almost inevitably causes anxiety to the patient unless explained very carefully.

## Other pleural lesions

Endometriosis may very rarely involve the pleura, causing haemopneumothorax associated with menstruation [222,223]. Transplantation of splenic tissue to the pleura, splenosis pleurae, has been described very rarely following abdominal injuries with rupture of the spleen [224]. They present as rounded pleural opacities.
